must have undergone certain changes, but still we had no explanation of why some children suddenly got hydrocephalus or why other children should be born with hydrocephalus. In order to get at the bottom of this question these cases should come under observation earlier than they did. Some of the cases were very advanced at the time of birth and others developed the condition gradually, and it was the latter cases that should be placed in the hands of the surgeon earlier. It was very disquieting to read the reports in European journals of repeated lumbar puncture as a cure of this condition; in his experience this procedure had not been attended with very brilliant results either in the obstructive or the nonobstructive forms of hydrocephalus. There were a certain number of cases of hydrocephalus that made spontaneous recoveries and some of the cases that did not get well under operative treatment recovered at the time the skull ossified. In other cases the process seemed to stop before ossification, so that we did not know why the process came to a standstill. Children that seemed to have an inflammatory process of the brain or meninges should be watched from birth. The results of puncturing the corpus callosum had not been as satisfactory in the congenital cases as one might wish.

Dr. WILLIAM SHARPE said that personally he had studied many cases of hydrocephalus and had made a report of forty-one cases to the Neurological Society in February, 1917. Of this series only fifteen were of the internal type of hydrocephalus, that was, cases in which the ventricles were blocked. Autopsy made on each of the cases that died (fourteen out of the total of forty-one cases operated on at that time), together with observations at operation, led him to believe that most cases of hydrocephalus were due to a former meningitis and a blocking of the stomata of exit of the cerebrospinal fluid in the cortical veins and sinuses and possibly lymphatics. If the iter or the foramina of Magendie and Luschka were blocked, that was merely an incident in the diffused process, as there were still other stomata of exit in the cortical veins and sinuses which were blocked, so that he felt that merely connecting the ventricles with the subarachnoid space by a callosal puncture was simply changing an internal into an external type of hydrocephalus and, therefore, little if any improvement could be expected. As Dr. Elsberg had demonstrated in the pictures, we might have the ventricles dilated with fluid when the iter was not blocked, so that merely puncturing the corpus callosum would surely not allow the fluid to get out of the spinal canal. The fluid must be given an exit beyond the cerebrospinal canal, that was, through the dura or into the blood stream itself. He was using a method of drainage for both the external and internal types of hydrocephalus through the dura into the subcutaneous areas of the scalp, by means of linen strands, the results of which had been very successful and seemed to demonstrate that the cerebrospinal fluid was absorbed in the subcutaneous tissues of the scalp. In his series of fifty-eight cases operated on by this method there were only seventeen deaths. The subject of hydrocephalus, however, was still in its infancy, and any procedure, even though it gave negative results, should be given consideration.

Dr. ISRAEL STRAUS said that in discussing this paper he thought it might be well to review the facts that had really been established. In the first place, he took exception to the statement that we did not know what the spinal fluid really was. Halliburton's article in a recent number of *Brain* showed the composition of the spinal fluid and that it was secreted by the cells of the choroid plexus. From the work of Cushman and Weed we knew that a certain amount of the fluid was of periganglionic origin and was poured into the subarachnoid space, but this amount was small. From these investigators it could be learned that the chief pathway of absorption was through the arachnoid villi into the superior longitudinal sinus. Dr. Elsberg had spoken of the obstructive form of hydrocephalus as being due to obstruction of the aqueduct of Sylvius. Schlapp and Gere stated in a recent paper that they had found an obstruction in the aqueduct of Sylvius which macroscopically consisted of tubercle-like swellings of the ependyma. We knew that under the ependyma was a layer of glia which was of the same embryonic origin as the lining of the spinal canal, the substantia gelatinosa centralis. It was simply the lining of the spinal canal and when changes occurred in it they were called central glyosis syringomyelia. Both of these processes had their origin in developmental changes, and it was the speaker's belief that similar changes occurred in the glia of the iter and caused the obstruction described by Schlapp and Gere. The reason Dr. Elsberg got some benefit from the procedure he had adopted in these cases was that it allowed more fluid to get into the subarachnoid space, where it might be absorbed by the villi into the longitudinal sinus. It seemed that the improvement that took place must be accounted for an physiological grounds. Dr. Straus also called attention to a form of hydrocephalus of infectious origin, an internal hydrocephalus, which might be due to a cerebrospinal meningitis which had led to a closure of the foramina of Magendie and Luschka. He believed that in such cases we should operate, for he did not believe that lumbar puncture would help them. He did not see why the pediatrician did not turn these cases over to the surgeon as early as possible, so that an opening could be made in the thickened meninges over the foramina of Magendie. Here he agreed with Dr. Sharpe that where we had a meningitic process the absorption through the arachnoid villi might be very poor. There were unquestionably cases of hydrocephalus in which no obstruction could be demonstrated by the physician and which were followed by early blindness and optic neuritis. These were generally of infectious origin, and in these every effort should be made to preserve the eyesight by surgical procedures.

Dr. GODFREY R. PISEK said that Dr. Elsberg had put the subject of hydrocephalus on a scientific basis, which was something that was needed. Many of the operative methods devised for the relief of hydrocephalus had failed and some had caused death because they disturbed the heat centers, were followed by a rapid rise of temperature, and a fatal ending. There was no doubt that by finding out the type of hydrocephalus by the various tests that might now be employed we would come to some type of operation that would benefit the patient. He had been impressed for a long time with the seeming groping in the dark in their treatment of hydrocephalus. They had felt obliged to resort to *some* method of treatment and had employed lumbar puncture, and some cases had apparently been cured by lumbar puncture; now they were in a position to decide what type of cases would be helped by this procedure. Dr. Koplik had referred to the fact that a certain number of cases were cured spontaneously and that this took place at the time of ossification. The speaker had taken measurements of the head in many cases of hydrocephalus and had noticed that the increase in size only subsided when ossification began. Dr. Elsberg did not speak of the mentality. To place the operation on the right plane it must be one that would improve not only the physical condition, but the mental condition as well.

Dr. ELSBERG, in closing the discussion, said he had excluded all varieties of inflammatory hydrocephalus from his paper because they formed an entirely different class of cases. He had not discussed the cause of hypersecretion, obstruction, or nonobstruction, but had only stated some of the facts brought out by recent investigations that showed that there were three different types of hydrocephalus. In eighteen out of forty cases diminished absorption from the arachnoid space was very marked and in such cases there was no reason for doing a puncture of the corpus callosum. The question that came up was how the absorptive power of the subarachnoid villi might be increased and that would be considered at another time. The fact that we could expect no benefit from a puncture of the corpus callosum in a case of hydrocephalus due to diminished absorption was the reason why we must determine whether a given case was due to obstruction or to lack of absorption. If it was due to obstruction at the iter, it might be benefited by puncture of the corpus callosum. When there was hypersecretion the only thing to be done was to relieve it by frequent punctures.

X-Ray and Radium in the Treatment of Skin Diseases in Children.—Dr. GEORGE M. MACKEE made this pres-

entation, which consisted of a lantern slide exhibit showing the effect of the *x*-ray and radium upon certain of the skin diseases of infancy and childhood. He stated that there were not many skin diseases peculiar to infancy and childhood that were amenable to treatment by these agents. One of the conditions frequently met with by pediatricians was favus or ringworm. This was a disease that had given a great deal of trouble in different parts of the world. It was much more difficult to treat in early life than when it occurred at the time of puberty. It had been almost eradicated in London and other European cities by the use of the *x*-ray and it seemed a pity that this method of treating it had not been more generally employed in the United States. Dr. Fordyce's clinic was the only free clinic in this city, so far as the speaker knew, in which the *x*-ray was employed in the treatment of ringworm, but every hospital and dispensary should be equipped to give this treatment; it could be given by a nurse under supervision. It was possible where there was but a single lesion to treat only the diseased area, it not being always necessary to depilate the entire scalp. In order to avoid scattering the hairs and thus the infection when depilation occurred, the lesion might be covered with zinc plaster after giving the treatment. Three weeks later the hair would fall out and by removing the plaster at that time the hair would be found adherent to it. In treating ringworm with the *x*-ray the dosage must be very accurately measured. It took a certain amount of *x*-ray to make the hair come out and a very little more to prevent its ever coming in again, so the limits of the dosage were not very wide. They had treated some 300 or more cases, the treatment being administered by three different men, and there had been no instance of permanent alopecia. In order that equally powerful *x*-ray treatment might be applied to all points on the surface of the skull, Adamson devised the method of mapping the skull into five areas and applying the *x*-ray to each of these areas successively. Protection was used for the face, ears, and neck. It took from one-half hour to forty-five minutes to treat the entire scalp. It was not necessary to treat all the areas on the same day or to apply a full depilating dose at one sitting; one might give a fractional part of the dose each day until the total dose was administered. If the correct dose was given the hair fell out in three weeks. The treatment could not be used in very young children, but only because they could not be kept still. A child of two or three years, however, might be treated very easily. The *x*-ray must not be applied to the scalp for several weeks after the application of irritating chemicals, and such chemicals must not be used for several weeks after the *x*-ray has been employed, because if this warning was disregarded permanent depilation might result. Other conditions that responded well to the *x*-ray were blastomycosis and actinomycosis. In vascular nevi good results were obtained with radium, but not so good with the *x*-ray. Cavernous angioma could be cured by the *x*-ray, but only by persistent treatment, and such persistent treatment was not advisable. In vascular nevi it was probably to the beta rays of the radium that the therapeutic results could be attributed. The radium tube, however, was not as satisfactory as the radium plaque, as it produced a reticulated effect. Portwine marks did not respond to the *x*-ray or radium. Pigmented nevi likewise did not do well under this treatment. Hairy nevi, on the other hand, responded well to *x*-ray treatment, as did also acne, though in the latter condition it was neither necessary nor advisable to resort to this method unless ordinary methods of treatment failed. In all forms of keloid both the *x*-ray and radium were very efficacious. The common wart, verruca vulgaris, was very amenable to treatment by the *x*-ray, one treatment with either one sufficing as a rule to effect a cure. The small, flat, juvenile warts did not do so well, while plantar warts which were not very satisfactorily treated by other methods responded well to the *x*-ray, and the speaker had never known a case so treated to relapse. Sarcoma was curable by this method if attacked early enough, that was, before metastasis had occurred. Dr. MacKee showed illustrations of several cases in which sarcoma was cured that had not recurred after periods of three years. Speaking of eczema, he said he did not wish to be understood as advocating the use of the *x*-ray as a routine method of treatment but in squamnous eczema it caused the lesion to disappear and it required only small doses to produce this result. However, he used the *x*-ray only in obstinate cases that failed to respond to the ordinary methods of treatment. Psoriasis occurred frequently in children and was easy to treat by means of the *x*-ray and radium; chrysarobin was, however, usually satisfactory. Lichen planus usually responded to ordinary methods of treatment. When it was limited to small areas, the *x*-ray or radium was indicated. Lupus vulgaris of hypertrophic or ulcerative type yielded well to treatment by the *x*-ray or radium. The atrophic type was very recalcitrant. If properly applied the *x*-ray gave good results in tuberculous adenitis and scrofuloderma might also be successfully treated in this way. There were a few more diseases in which the *x*-ray and radium were an aid, but, as they were comparatively rare, they would not be considered at this time.

Dr. Fred Wise said that in regard to the *x*-ray in the treatment of tinea favosa and ringworm, it might be said that if the *x*-ray had accomplished nothing else than to cure ringworm, it would be entitled to the greatest respect as a therapeutic agent. To cure ringworm in one-half hour, when by other methods of treatment, even under the care of the best nurses and dermatologists, it took two and one-half years, was certainly an achievement worthy of note. With regard to nevi, all pediatricians saw these lesions and knew that some nevi got well without treatment. At the dispensary the first question they asked when they got a case of nevus was whether it was getting larger or smaller. If it was not increasing in size, they told the mother to let it alone and return in a year; this advice did not apply to portwine stain. Phenol or trichloracetic acid was sometimes as good as radium or the *x*-ray and perhaps better for the portwine stain, but the best treatment was carbon-dioxide snow. Keloids, as the speaker said, were amenable only to treatment by the *x*-ray. The case of warts in the elbow flexure ought to be of interest to the pediatrician. This was an ordinary lichen planus simplex or lichen chronicus circumscriptus, an exanthematous eruption frequently limited to the neck and the elbow and knee flexures. Later on these peculiar warty formations developed at the site of the lichen in children. Dr. Wise said he had seen two cases of sarcoma cured by the *x*-ray. As to psoriasis, he seldom had occasion to employ the *x*-ray. The lesions of lupus vulgaris and scrofuloderma were due to the presence of the tubercle bacilli and were difficult to cure. The Finsen light had been used extensively in Europe and the *x*-ray probably accomplished more good in some forms of tuberculous lesions than all other forms of therapeutic measures hitherto devised. It was difficult to cure prurigo and chronic papular urticaria; occasionally divided doses of *x*-ray applied to the extremities would do more good than any form of dietetic treatment, and these cases should be treated locally, that was, those that did not respond to dietetic treatment. Certain affections, such as xeroderma pigmentosum and a few other rare conditions sometimes seen in children, had responded favorably to *x*-ray treatment.

Dr. Bowleslaw Lapowski said he had been in favor of establishing clinics such as had been suggested for the treatment of ringworm and had suggested this to Dr. Emerson, but the finances of the Health Department would not permit of the establishment of such clinics at the present time. He had never treated psoriasis with the *x*-ray. It was not a question of making the lesions disappear for the time being, but of producing permanent cure. He thought the *x*-ray treatment as likely to be followed by relapse which would be very resistant to treatment. The *x*-ray had a place in surgical diseases. Etiologically eczema was not a dermatosis and the *x*-ray was not indicated as the logical treatment. In the treatment of nevi or any skin disease in children he thought it was not well to draw conclusions until later in life, for we did not know what the subsequent developments might be.

Dr. Sidney V. Haas said he wished merely to say that there was one more clinic such as Dr. MacKee had suggested in New York City and that was at the Home for Hebrew Children.

Dr. MacKee said that he agreed with Dr. Lapowski's insinuations to the effect that the *x*-ray might produce harmful results in after years. The speaker said that all roentgenologists were acquainted with the various complications and sequelæ of the *x*-ray and knew how they could be avoided. Radium and the *x*-ray should not be employed excepting by experts and they should not be used when other remedies sufficed to effect a cure. Dr. Lapowski expressed himself as opposed to the use of the *x*-ray and radium in eczema and psoriasis because he thought the diseases were made more rebellious thereby. The speaker had never encountered such a phenomenon, but, nevertheless, these agents should not be employed in such diseases unless other methods of treatment failed.

SECTION ON MEDICINE.

Stated Meeting, Held October 16, 1917.

Dr. Harlow Brooks in the Chair.

This program was from the Base Hospital, 77th Division, National Army, Camp Upton, Long Island.

The Administration of an Army Base Hospital.—Major J. D. Whitman made this contribution. He said that the subject was a rather difficult one to discuss at the present time owing to the fact that the entire organization of the Army was in a transitional stage. We were by degrees adopting the organization and methods of our British and French allies. No information had been furnished them at this time of the exact personnel which the base hospital which they were establishing would have. The administration of a base hospital was carried on through two divisions: one administrative, the other professional. The administrative division was subdivided into an adjutant's office, registrar's office, quartermaster's office, the hospital mess, the office of the commanding officer of the detachment of the medical department, the officer of the day, the officer of the guard, and the chaplain. The adjutant's office, normally in charge of the major of the Medical Corps, had charge of the administrative records and correspondence, the telegraph office, the telephone exchange, and the postoffice. It was through the adjutant that the commanding officer communicated with the officers and men of his command. He was the representative of the commanding officer and the executive officer of the hospital. The registrar's office had charge of the medical and surgical records of all patients treated in the hospital. The office was also charged with the proper care of the money and valuables of the patients. The quartermaster's office had charge of all quartermaster, medical ordnance, and signal corps property and funds, the construction and repair of buildings, of transportation, the police, and care of the grounds, disinfecting, laundry, heating, lighting, ice plants, and the clothing and baggage room of patients. The quartermaster's department was directly responsible for every article of property which the hospital had. The hospital mess included the kitchens, bakery, and special diet service. It was administered by a captain or a lieutenant of the Medical Corps, with a large number of cooks and female dieticians. The mess officer was accountable to the commanding officer. The commanding officer of the detachment of the Medical Department acted in the capacity of company commander for the detachment on duty at the hospital. He was responsible for all records, returns, and muster rolls pertaining to his detachment and was over all matters of discipline. The officer of the day was detailed each day from the roster of medical officers and was in charge of the guard, receiving office, the roster of patients, the ambulance, emergency and fire alarm service, and the information office of the hospital. The tour of duty of the officer of the day was twenty-four hours, and during that time he must always be accessible for cases of emergency. In time of peace the hospital was guarded usually by medical department men detailed as watchmen; in time of war such guard duty was ordinarily performed by a permanent detail of sanitary troops. The professional division of a base hospital was divided into the various services with a major of the Medical Corps known as the chief of the medical service; the surgical service with its chief; a section of surgery of the head with its chief, and various other services, as the laboratory, *x*-ray, dental, and nursing services. Great efforts were being made to secure for this work as many specialists in all branches for duty at base hospitals as it is possible to obtain. The section on surgery of the head was again divided into an eye service and an otolaryngological service. There are also sections charged with psychiatry, with neurology, with genitourinary diseases, and in some instances a section devoted to diseases of the skin. In addition to these, base hospitals would have the services of visiting specialists on diseases of the lungs, cardiovascular system, orthopedics, and other branches. Every effort was being made to obtain efficient male and female nurses, orderlies, experienced pharmacists, laboratory assistants, dieticians, etc. Many of these were found among the members of the National Army, but the task of organizing and assigning these enlisted men was a very difficult one. In the hospital under construction at Camp Upton there were seventy buildings. At present the hospital was occupying barracks which they had subdivided into wards and offices. There was every reason to feel proud of the success that had attended the efforts of the medical department of the Army to supply medical and surgical supplies for our great camps. A physician entering the military service was compelled through necessity to do without many drugs and surgical appliances which he had been accustomed to use in his practice, but the base hospitals as equipped at present throughout the United States had all the essentials necessary for careful and thorough study and efficient treatment of all patients.

First Psychiatric Experiences at the National Army Cantonment at Camp Upton, Long Island, N. Y.—Dr. A. J. Rosanoff read this paper, in which he called attention to the way in which the scope of psychiatry had broadened within the last decade or two. It was formerly thought that the work of the psychiatrist was confined almost entirely to institutions for the insane and mentally defective, whereas it was now realized, at least by psychiatrists, that the material which reached an institution was but a small part of the whole. The most urgent and practical problems of prevention and treatment in psychiatry were not to be solved in institutions, but in the community at large. The experiment of conscription had caused a prompt cropping out of cases that arranged themselves in three main groups: (1) Drug and alcohol habitués coming to light within a day or two following arrival at the camps, through symptoms of abstinence. (2) Cases of epilepsy observed in convulsions at the camps. (3) Various types of constitutional inferiority coming to light through hysteroid manifestations and through malingering, or perhaps more correctly semi-malingering. The drug cases were almost exclusively heroine cases. The draft constituted an unrivalled opportunity of obtaining with full accuracy the prevalence of drug habits in the male population of draft ages in the districts from which the Camp Upton troops had been supplied. In the writer's opinion the great majority of users of alcohol were not drug habitués in the specific sense of that term, but he had long suspected that in some cases true addiction developed, followed by typical symptoms of abstinence, a state characterized by restlessness, insomnia, sweats, chilly sensations, intense craving, and perhaps fatal attack of delirium tremens. The cases of epilepsy among drafted men required no comment as they were soon discovered and weeded out. Malingering was common, and attention was given these cases as possible simulation of mental disorders. In the cases of semi-malingering, the question was not how much of the condition was due to malingering nor even what degree of true abnormality existed, but whether or not the recruit was fit for military service. The writer said he knew of no test or system of tests whereby this question could be determined, with full protection against error, either to the service or to the individual, other than the test of actual service. It might be a surprise to the audience to hear that they had already had a number of cases of shell shock among the recruits, though most of them had not seen a shell. Shell shock was a handy term applied to a host of heterogeneous conditions many of which had little or nothing to do with the explosion of shells. Perhaps the best justification for using this term was in

connection with acute recoverable, hysteriform attacks, actually determined by the fright or other upsetting effect of shell explosions. Exactly the same kinds of attacks had been witnessed by our own medical officers in the course of physical examinations. The new environment, the bewildering effect of the numerous procedures, the apprehension of what was to follow, etc., being responsible. These cases were not necessarily rejected at the outset, but were often submitted to the test of service which would usually reveal real and permanent unfitness in many of them. It was equally true that in some the effect of routine discipline and training would be one of gradual adjustment and the ultimate development a good soldier. To put the matter in a nutshell, the aim of the psychiatrist in examining recruits was not, as in civil life, a finesse of diagnosis, but to reach trustworthy judgments as to mental fitness for active military service.

Dr. HARLOW BROOKS said that it had been perfectly astonishing the amount of psychiatric material that had come out in the camp which would not have been recognized in the course of routine office practice in civil life. At present he was much interested in seeing what was going to become of a number of cases that had been taken in temporarily.

The Interpretation of the Schick Reaction in Recruits for the National Army.—Dr. ABRAHAM ZINGHER made this contribution, in which he said that the work with the Schick test had now been carried on for about four years and was generally accepted as a reliable test of the susceptibility of children to diphtheria. In children one was not confused by the socalled pseudoreaction, but in adults a large number showed a pseudoreaction. This pseudoreaction was not due to the toxins of the diphtheria bacilli but to the protein contained in the solution. In order to determine whether a reaction was a true reaction or a pseudoreaction the following procedure had been adopted: Heating the diphtheria toxin to 75° C. destroyed the diphtheria toxin but did not appreciably affect the autolysed protein of the diphtheria bacilli, and it was the latter which caused the pseudoreaction. The outfit for controlling the positive, pseudo, and combined reactions was similar to the Schick test outfit, with the exception that the toxin in the capillary tube had been heated to 75° C. The dose, as was well known, was one-fiftieth the lethal dose for a guinea pig in one-fifth of a cubic centimeter of salt solution. The Schick test was made in the usual way on the right forearm and at the same time the test for the pseudoreaction was made on the left forearm. In an individual who gave a positive reaction only, the control test with the heated toxin would be negative. Where there was a pseudoreaction the control reaction would be of about the same size and appearance, and pass through the same clinical course as the original reaction; both reactions reached their height in twenty-four hours and disappeared in ninety-six hours. In an individual who gave a combined reaction, both the positive and the pseudoreaction might be detected. The positive reaction became manifest at the end of three or four days, when the pseudoelement had disappeared. At Camp Upton they had made the original Schick test and the control tests on 1,165 men and found the proportion of negative reactions was 72.8 per cent. A pseudoreaction occurred in 12.2 per cent.; in other words, 85 per cent. of this series of men were immune to diphtheria and 15 per cent. were susceptible. Another series of 1,483 men subjected to the same tests gave very much the same results. The point he especially wished to bring out was that the pseudoreaction could be very definitely awakened by using the heated toxin on the left arm and the regular toxin on the right arm. The question of diphtheria in adults had to be considered in view of the fact that outbreaks of diphtheria had been reported from European camps and there had recently been an outbreak of this disease among the troops at Newport. It was of great value to have a method of determining which soldiers were protected against diphtheria, as this information would result in a great saving of antitoxin, since it would be necessary to immunize only 15 per cent. of the men and one would not need to worry about the remaining 85 per cent. There was some question as to whether this general application of the Schick test would be practical in view of the fact that there was already such a large amount of vaccination to be done in the army. But when one recalled that in New York City there were from 1,300 to 1,500 deaths from diphtheria every year and the population of the United States was about twenty times that of New York City, so that the mortality from diphtheria in the United States was probably from 2,500 to 3,000 a year, it was evident that the control of diphtheria was still in its infancy. Dr. Zingher said there were interesting problems in connection with natural immunity. In a series of 11 mothers who gave a negative test and were immune to diphtheria just after the birth of their infants, a second Schick test six months later showed them still negative and still immune. The 11 children of these mothers also gave a negative reaction to the Schick test just after birth, but at the second test, six months later, they all gave a positive reaction, that was, they had lost the immunity which they had brought over from the mother. These children were given the three doses of toxin antitoxin for the purpose of immunizing them and after that they all gave a negative reaction and were immune. Other experiments showed that when the mother was susceptible to diphtheria the infant was also susceptible just after birth, but if both mother and child were given the immunizing dose of toxin antitoxin, both developed negative reactions and were immune to diphtheria. From their observations they might conclude that practically all children under one year of age were susceptible to diphtheria, even though they gave a negative reaction to the Schick test at the time of birth. Children not susceptible at the time of birth become so later. The mortality from diphtheria greatly increased at the age of six to nine months, being greatest at nine months; from this age up to the second year laryngeal diphtheria was especially frequent. The immunization of young children might be greatly simplified by leaving out the Schick test entirely and giving instead the immunizing doses of toxin antitoxin. The general immunization of young children against diphtheria was a matter that depended upon the general practitioner. He must recognize its value and recommend it if it was to become popular. The local and constitutional reaction from the administration of the toxin antitoxin was less in infancy and became more marked with increasing age. Dr. Zingher said he had gone into the subject of immunization in infancy simply to show how the population might be protected against diphtheria. It has been found that 95 per cent. of those who gave a positive Schick test could be actively immunized against diphtheria and retained their immunity afterwards. Among the men in the army camps there was a good deal of tonsillitis and other throat infections, and if they knew that a soldier was immune to diphtheria that disease could be excluded even without a bacteriological examination.

Dr. CHARLES F. COLLINS said he would like to ask a few questions. One might have diphtheria carriers and yet the Schick test would always be negative. In St. Luke's Hospital they had not had a single case of diphtheria arise in a subject who had given a negative Schick test on admission. They had had one adult under their care who gave a negative Schick test and five months afterward developed diphtheria and had a severe type of the disease. They also had another case of diphtheria in a person who had given a negative Schick test, so the question he would like to ask was whether these persons who gave negative Schick tests were also carriers. So far as he was concerned he would not hesitate to keep a child who gave a negative Schick test in a ward with diphtheria, though, of course, hospital authorities did not permit this and as soon as a case of diphtheria developed it was quarantined. Personally, however, he believed that a child with a negative Schick reaction would not develop diphtheria unless he was also a carrier. Another question he would like to ask was how long one might depend upon a negative Schick persisting? Personally he understood the test should be made once a year; he tested himself once every eight or ten months to learn whether he kept his immunity.

Dr. ZINGHER, in closing, said that at the Willard Parker Hospital during the last four years they had tested every child with scarlet fever; 1,200 children with scarlet fever gave a negative Schick test and not

one of these developed diphtheria, although 15 or 20 per cent. of them became carriers. The test was perfectly reliable if a uniform technique was used and standard solutions of toxin, and a uniform interpretation of the test was applied. If under these conditions the child gave a negative Schick reaction one could come to a decisive conclusion as to whether an exudate was diphtheritic or not. We might have an individual who was constitutionally protected against diphtheria and who was still a carrier; such an individual would not develop the disease unless the local resistance was broken down, which might happen as the result of a tonsillectomy or of an operation on the nose, or a cold, when he might develop diphtheria. This would show that we must have a local as well as a constitutional protection. The duration of the immunity conferred by the toxin antitoxin injections was a very important matter, and whether we could depend upon a single course of immunizing doses to confer permanent immunity. He believed that we could depend upon the permanency of such immunization. After a child had become susceptible and then developed immunity he always showed a persistently negative Schick reaction. If we examined the blood serum we would find an almost constant amount of antitoxin and we would find this amount persistent in subsequent tests. It was of extreme value to be able to immunize physicians and nurses in contagious disease hospitals with the three doses of toxin antitoxin.

Dr. HARLOW BROOKS said it was surprising how little contagious disease they had in the camp. They had had about ten cases of measles, but no secondary infections. They had had one case of pertussis and one case of leprosy. There were quite a number of cases of tuberculosis, but they had come to the camp with the disease; it had not been developed in the camp. At the present time they had 128 cases in the base hospital out of a camp population of 28,000, which he thought was a remarkably good showing.

The Reactions Produced by Prophylactic Inoculation with So-Called Triple Typhoid Vaccine.—Captain RUSSELL L. CECIL, Director of the Laboratory at Camp Upton, made this presentation. He stated that during the last three weeks 30,000 recruits had been inoculated with the so-called triple vaccines of typhoid, paratyphoid-A and paratyphoid-B, the mixture consisting of equal parts of these bacteria. The reason the paratyphoid vaccine had been added was because in the recent mobilization of the troops on the Mexican Border there was considerable paratyphoid fever among them. The vaccination with the typhoid vaccine had been so successful that there was every reason to believe the paratyphoid vaccination would be just as successful. While the opportunity of trying out the paratyphoid vaccine in Texas and Mexico was not large, the results were so successful that it was decided to introduce the paratyphoid vaccine into the National Army. In Texas and Mexico only the paratyphoid "A" vaccine was used, as paratyphoid "A" was the type which occurred. The triple vaccine was prepared at the Army Medical School in Washington in the usual way. The number of bacteria was estimated, the bacteria killed by heat, and the vaccine preserved in 0.5 per cent. phenol. One-half a cubic centimeter, or 500 million killed bacteria, were used for the first dose and twice that number for the second and third doses. One might think that in giving the triple vaccines, containing three times as many killed bacteria as the typhoid vaccine alone, there would be a much more marked reaction than with the plain typhoid vaccine alone, but this was not the case. As to the technique used, the recruits were lined up as they came through the room, stripped to the waist, and an assistant swabbed the area in the posterior axillary fold with tincture of iodine. Another assistant filled a 5 c. c. Record syringe with vaccine. The needle was not sterilized after giving each injection but was wiped off with 95 per cent. alcohol. As to the reactions, Dr. Cecil said that he had seen only 38 patients with a reaction sufficiently severe to make them come into the hospital. The local reactions were almost identical with that of the typhoid vaccine. There was a small indurated area, hot and swollen, and sometimes an enlargement of the axillary lymph glands. Just a little more than one out of every 1,000 men became sufficiently ill to be sent to the hospital; if the others had any constitutional reaction it was not sufficient to require medical attention. In looking over the records it seemed that the most prominent symptom was fever, which occurred in 66 per cent. of the cases; in only 33 per cent. did the temperature rise over 100° F. Prostration was present in practically all of these cases. The next symptom in frequency was headache, which was present in 44 per cent.; there was muscular pain in 34 per cent. and backache was almost as frequent. Nausea was quite common, particularly after the second inoculation. Dizziness and chilliness occurred less frequently. There were only two cases with definite chills. It might be said that as a rule the after effects of the vaccines were so small as to be negligible. Colonel Craig studied 50 cases in which he used the same vaccine as was now being used at Camp Upton, and he found that 32 per cent. of those inoculated showed a rise in temperature after the first inoculation, 86 per cent. after the second and only 18 per cent. after the third. Twenty per cent. complained of headache. Craig also made agglutination tests after the inoculation; 28 days after the first inoculation he found high agglutination titres for all three organisms. From his experience at Camp Upton, Dr. Cecil could advocate the use of the triple vaccine. Many of the men who came to the hospital with reactions after the inoculations were able to go out after 24 hours as the symptoms disappeared very rapidly after rest in bed. Another question which interested them was what the effect of the inoculation was on those who had been tuberculous. It had been claimed that the inoculations sometimes lighted up an old tuberculous process or some other infection. No case of this kind had come under their observation as yet, but the inoculations had been instrumental in bringing on an attack in a case of epilepsy. They had used the triple vaccines only in men under 45 years of age; in the older men they had used only the paratyphoid vaccines. In conclusion it might be said that from the practical standpoint there was every reason to believe that the paratyphoid vaccines would be just as effective against paratyphoid fevers as the typhoid vaccine had been against typhoid fever.

Dr. HARLOW BROOKS said he had been interested in the typhoid vaccinations at Camp Whitman. There they had a much smaller group of men and the reactions were more numerous and more severe with the typhoid vaccination alone than they had been at Camp Upton with the triple vaccines.

Dr. ALFRED MEYER said he would like to ask Dr. Cecil if he had had any skin lesions as a result of the vaccinations with the triple vaccines. In one large hospital it was reported that the nurses decided to oppose typhoid vaccination among themselves because a number of them had had eruptions and skin lesions after inoculation and they claimed that the inoculations were responsible. When the work of inoculating the nurses was to be begun at Mount Sinai Hospital Dr. Meyer said he was appointed to speak to the nurses on the subject, as there was some opposition to the inoculations on these grounds. Personally, Dr. Meyer said he had had no experience of that kind, in spite of the fact that the work has gone on for some years, and he would like to know whether any such lesions had occurred among the soldiers.

Dr. CECIL, in closing, said that he had not seen any case of skin disease develop as the result of the typhoid vaccines. He recalled one case which occurred in Philadelphia of a nurse who developed a peculiar eruption after the second inoculation; it was thought at first that she had a septicemia, but it proved not to be, and the patient recovered.

Dr. MEYER asked Dr. Brooks whether there was any modified form of emetine used on the cases of amebic dysentery which Dr. Murphy was to have reported. He was interested in knowing whether Dr. Murphy had tried the modified form of emetine known as emetine bismuth iodide. Personally, he had tried this preparation in but one case that had frequently relapsed after emetine hydrochloride, but thus far after the bismuth iodide there had been no relapse in four months. This was the reason he was interested in learning whether Dr. Murphy had had any experience with this new preparation.

Dr. BROOKS said that it was to be regretted that Dr.

Murphy could not be present, as he had some very interesting experiences with amebic dysentery. They had used the preparation mentioned with precisely the results that Dr. Meyer had spoken of. They were at first apparently brilliant, but later there would be relapses.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PHYSICAL REMEDIES FOR DISABLED SOLDIERS. By R. FORTESCUE FOX, M.D., with chapters by Major R. TAIT MCKENZIE, R.A.M.C.; FRANCIS HERNAMAN-JOHNSON, M.D., and JAMES B. MENNELL, M.A., M.D. 277 pages. illustrated. Published by William Wood & Co., New York. Price, $2.75.

WHITE AND MARTIN'S GENITO-URINARY SURGERY AND VENEREAL DISEASES. By EDWARD MARTIN, A.M., M.D., F.A.C.S., BENJAMIN A. THOMAS, A.M., M.D., F.A.C.S., and STIRLING W. MOORHEAD, M.D., F.A.C.S. Tenth edition, 929 pages, illustrated with 422 Engravings and 21 Colored Plates. Published by J. B. Lippincott Company, Philadelphia and London. Price, $7.00.

THE PRACTICAL MEDICINE SERIES, Vol. 6, GENERAL MEDICINE. Edited by FRANK BILLINGS, M.D., and BURRELL O. RAULSTON, M.D. 347 pages, illustrated. Published by The Year Book Publishers, Chicago, Ill. Price, $1.50.

THE ORGANS OF INTERNAL SECRETION. By IVO GEIKIE COBB, M.D. 228 pages. Published by Wm. Wood and Company, New York. Price, $2.00.

LIGATIONS AND AMPUTATIONS. By A. BROCA. Translated by ERNEST WARD, M.D. 285 pages, illustrated. Published by Wm. Wood and Company, New York. Price, $3.00.

THE PRINCIPLES OF GYNÆCOLOGY. By W. BLAIR BELL, M.D. Second edition, 551 pages, illustrated. Published by Wm. Wood and Company, New York. Price, $6.50.

KIRKES' HANDBOOK OF PHYSIOLOGY. By CHAS. WILSON GREENE, A.M., Ph.D. Ninth American revision, 790 pages, illustrated. Published by Wm. Wood and Company, New York. Price, $3.75.

CLINICAL SURGICAL DIAGNOSIS. By F. DEQUERVAIN. Second edition, 841 pages, illustrated. Published by Wm. Wood and Company, New York. Price, $10.00.

PROBLEMS OF SUBNORMALITY. By J. E. WALLACE WALLIN. 485 pages. Published by the World Book Company, Yonkers-on-Hudson, New York. Price, $3.00.

STATE DEPARTMENT OF HEALTH OF NEW YORK. THIRTY-SIXTH ANNUAL REPORT, for the year ending December 31, 1915. 3 Volumes. Published by J. B. Lyon Company, Printers, Albany.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints. Volume 28. 559 pages. Illustrated. Published by the Rockefeller Institute for Medical Research, New York.

THE CLINICAL PATHOLOGY OF THE BLOOD OF DOMESTICATED ANIMALS. By SAMUEL HOWARD BURNETT, A.B., M.S., D.V.M. Second edition, revised and enlarged. 166 pages. Illustrated. Published by the Macmillan Company, New York. Price, $2.25.

A HANDBOOK OF ANTISEPTICS. By HENRY DRYSDALE DAKIN, D.Sc., F.I.C., F.R.S.. and EDWARD KELLOGG DUNHAM, M.D. 129 pages. Illustrated. Published by the Macmillan Company, New York. Price, $1.25.

ELEMENTS OF HYGIENE AND PUBLIC HEALTH. By CHARLES PORTER. 411 pages. Illustrated. Published by the Oxford University Press, American Branch, New York. Price, $4.15.

IMPOTENCE AND STERILITY, with Aberrations of the Sexual Function and Sex Gland Implantation. By FRANK LYDSTON, M.D., D.C.L. 333 pages. Illustrated. Published by the Riverton Press, Chicago. Price, $4.00.

SURGICAL NURSING IN WAR. By ELIZABETH R. BUNDY, M.D. 184 pages. Illustrated. Published by P. Blakiston's Son and Company, Philadelphia. Price, 75c.

Therapeutic Hints.

Internal Treatment of Psoriasis.—P. Duret offers the following combination to be administered by intramuscular injections for the treatment of psoriasis:

℞ Precipitated sulphur (washed)..0.002 g.
Guaiacol (crystallized) .....0.10 g.
Camphor (refined) .....0.10 g.
Eucalyptol .....0.20 g.
Olive oil (purified and sterilized to make .....1 cc.

The sulphur is dissolved in the oil by mild heat, and while warm this is poured into the mixture previously made of the camphor and guaiacol, and then the eucalyptol added. The sulphur solution must not cool until the mixture is completed, in order to prevent precipitation. This preparation remains stable at ordinary temperatures, and an injection of 3 c.c., afterward 5 c.c., is practically painless. This is due to the analgesic effect of the combination of camphor and guaiacol, and the rise of temperature following the injection is controlled by the antipyretic effect of the guaiacol.—*Journal des Practiciens*, July 21, 1917.

Treatment for Chilblains.—J. B. Anderson gives the following treatment for this unruly condition; Apply a coating of linseed oil for three successive nights, letting the oil dry in the skin, and then putting on a pair of stockings to protect the bedding. On the fourth night, bathe the feet in hot water. He further states that thereafter there will be no trouble with chilblains.

Mistura Antifebrifuga.—Children's Hospital Fever Mixture is prepared as follows:

℞ Potassium citrate.....4 gm.
Spirit of nitrous ether.....15 mils.
Syrup of lemon.....15 mils.
Solution of ammonium acetate....60 mils.
Distilled water to make .....100 mils.

M. Sig.—Teaspoonful every two or three hours. —*Journal American Pharmaceutical Association.*

Relief for Dyspepsia.—While the following pill is not new, its age speaks for the beneficial effects of the combination. It acts both as an aperient and stomachic tonic, at the same time stimulating gastric secretion:

℞ Ipecac. pulv.....gr. ss.
Extract. rhei.....gr. ij.
Extract. nucis vomicæ.....gr. ss.

M. et Sig.—To be taken half an hour before food, two or three times daily.

Vomiting of Pregnancy.—Shaw has had beneficial results from the following in this condition:

℞ Menthol .....℥j.
Alcohol .....℥j.

M. Sig.—Five drops every one, two or three hours as required.—*Ellingwood's Therapeutics.*

Neuralgia.—N. F. Howard offers the following formula for relief in all forms of neuralgia:

℞ Ammon. muriat.....℥iij.
Tinct. belladonna.....℥j.
Tinct. hyoscyami.....℥ij.
Aq. menth. piperit.....℥iv.
Aq. camphor.....℥x.

M. et Sig.—One-half to one teaspoonful in a little sweetened water every two or three hours.

SHOULD CERTAIN TUBERCULOUS PATIENTS WORK?*

BY MAURICE FISHBERG, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING PHYSICIAN, MONTEFIORE HOME AND HOSPITAL FOR CHRONIC DISEASES.

DISCUSSING the treatment of tuberculosis, the classical authors speak of exercise in the open air, hill climbing, long sea voyages, and working generally, as beneficial for consumptives.

Perfect rest for the tuberculous was not advocated as beneficial for every patient by Morton, Laennec, Louis, Trousseau, Sydenham, Stokes, Lebert, Walshe, Brehmer and most of other pioneers in the clinical study of tuberculosis. And they were excellent physicians; their clinical observations on the symptomatology, course and physical signs of the disease are periodically rediscovered by modern specialists. And just as I find their clinical observations useful to-day, so I am willing to accept their opinions on the effects of certain methods of treatment on the course of phthisis. Moreover, they treated active tuberculosis, not the sort which we at present call "early" or "incipient" cases, a large proportion of whom are not at all sick with active tuberculous disease. Yet they observed that in many cases exercises were beneficial in the treatment of phthisis. Indeed, from the statistics they published, it appears that the percentage of recoveries among their patients was not much lower than we attain at present using the modern method of rest cure.

Brehmer was apparently the last to advocate walking exercises and hill climbing as excellent adjuvants in the treatment of phthisis. But his pupil Dettweiler introduced the rest cure *(Liegekur, Kadaverruhe)*, and during the past thirty years it has been the method applied in nearly all sanatoriums in Germany, and from there it has spread all over the civilized world, to every country where attempts have been made to treat tuberculosis methodically and effectively.

The "rest cure" has become a dogma in modern phthisiotherapy, and it is carried out more or less rigorously in nearly all sanatoriums. As is usual with medical dogmas, this has been completely adopted by the laity, and, with the proclivities common to the sick, tuberculous patients fear exercises more than any other real or alleged deleterious agent.

*Read before the New Jersey Joint Conference on Tuberculosis, Nov. 9, 1917.

Acute exacerbations, extension of the disease process, fever, hemoptysis, cough, anorexia, etc., are each and all often attributed to exercise, be it ever so mild, and for this reason it is shunned religiously by all who have been in institutions, and by many for many years after the focus in the lungs has cicatrized. As a result we meet with numerous patients in sanatoriums who are to all external appearances healthy, well fed and often quite vigorous, yet they idle away their days for months in the institutions, and when finally discharged as cured, or with the disease arrested, they indefinitely remain fearful of work. As Hermann Biggs puts it tersely, the sanatoriums often convert sick workmen into healthy loafers.

Reaction Against the Indiscriminate Application of the Rest Cure.—One of the most important reasons for the universality of the rest treatment as a panacea in phthisis is undoubtedly the fact that it is simple, and when applied in all cases a great deal of the work which individualization in therapeutics might entail is done away with. The superintendent who applies the rest cure indiscriminately has solved the most difficult problem of treatment to his own satisfaction and well being, and has an easy time in running his institution smoothly.

But at present an important complication has arisen which compels executive officers of public sanatoriums to take stock again and to inquire whether some of the tuberculous patients in their care may not be made to do some useful and productive work with benefit to themselves, the institutions and the communities. The shortage in labor during the past three years is felt everywhere, and sanatoriums find it hard, often impossible to obtain sufficient help to run institutions properly. To solve this problem many have attempted to induce some of their patients to do some work in the wards and grounds of the institutions. It appears, however, that in the majority of cases the superintendents have failed in their efforts along these lines. In some sanatoriums a large proportion of the patients, when told that they can and must do some work, leave soon after admission; in others there have been strikes—the patients united and refused to do anything.

In one sanatorium, in which I recently investigated this problem, some patients told me that if they were really fit for work they would rather do it in the city where they would be paid for their labor; others told me that they were convinced that fever, hemoptysis, etc., would follow the slightest exertion. In fact, they volunteered to produce cases which were thus adversely influenced by work. I should mention right here that in many

respects these patients were right when refusing to work. The order of the superintendent was to the effect that one-half the patients in each ward should do certain tasks one day, and the other half the next day. Here again, when attempting to place patients to work, no attempt was made at individualization, and if it had been carried out considerable harm might have resulted to some patients.

This reaction against the universal rest treatment of phthisis is, however, bearing fruit of late, Many voices are heard from physicians entitled to authoritative opinion against its abuses; the dangers to the individual patients, and the burdens it imposes on the community are beginning to be appreciated. We now read articles published in medical journals in Europe and America that it is time that our tuberculous patients should be individualized in regard to rest and exercise. In England Paterson and Inman have introduced the method of "graduated labor"; in France the *cure de travail* is strongly urged, and even in Germany *Uebungstherapie* is again recommended for many tuberculous patients.

Attempting to individualize our tuberculous patients as regards their ability to work more or less, we find that they may be classified into the following three groups:

1. *The Acute and Subacute Progressive Cases.*—Those affected with active and progressive diseases, irrespective of the extent of the lesion discovered in the lungs; those who cough, expectorate, have fever, rapid pulse, dyspnea, and lose weight very quickly, cannot and should not work. Their rapidly wasting muscles should not be exercised; their myocardium and nervous systems are profoundly affected by the tuberculous toxin, and only perfect rest may afford them an opportunity to reduce the toxemia and carry them over the acute stage, when the process in the lungs may finally become localized, drainage established, and the disease is arrested in its acute or subacute course.

This class of cases will not be discussed here. They constitute but a small minority of the sanatorium patients, because those showing symptoms of such activity of the disease are either not admitted to institutions or, when admitted, they are soon discharged under the plea that they are not suitable for sanatorium treatment. They cannot work, nor can they perform any exercises without harming the slim chances of an improvement in their condition. Perfect rest is best in their cases, and it is deplorable that they are not admitted to institutions in which this method can be effectively applied; much better than in the average poor or even well-to-do home.

2. *The Conventional Incipient Cases.*—The second class of patients consists of those who show physical signs of tuberculous lesions in the lungs, usually tubercle bacilli in the sputum, but few or none of the constitutional symptoms of phthisis. A very large proportion of the patients in sanatoriums aiming at admitting none but "incipient" cases consists of this class. They are more or less robust looking, their appetite is good, and they have hardly any fever, tachycardia, dyspnea, etc., and they gain in weight and strength soon after admission. As will be shown later on, most of these patients can and should work more or less, and idleness, which is the concomitant of the perfect rest cure, does many of them more harm than good.

3. *Advanced Cases.*—The third class of cases consists of patients showing signs of extensive tuberculous disease of the lungs, mostly bilateral. A large proportion suffer from the constitutional symptoms of phthisis and cannot work, or they may feel quite well while resting but the least exertion results in fever, tachycardia, dyspnea, etc., and they are unable to do anything without harming themselves. Among these are also to be included phthisical patients in the terminal stages of the disease.

But with many patients showing signs of extensive disease the contrary is true. As will be shown later on, the ability of these patients to work does not depend so much on the extent of the pathological process in the lungs, but solely on the constitutional reactions called forth by exercises or work.

Discussing the cases fit for various degrees of work, we leave out of consideration those suffering from acute or subacute febrile tuberculous disease, irrespective of the stage in which they may be classified. They are acutely sick and are no more fit for exertion or even walking than are patients suffering from pneumonia, typhoid, or acute articular rheumatism. At the present state of phthisiotherapy, we have but one weapon to combat the toxemia in these patients—rest, and it should be applied thoroughly.

Deleterious Effects of Prolonged Rest.—But not all the patients in the second and third groups mentioned above are benefited by the rest treatment. They all show physical signs of phthisis, to be sure, but not all suffer from the constitutional symptoms of the disease. An analogy with our present methods of caring for cardiac patients will make our point clear. Is there a rational physician who would enjoin perfect rest for months for all persons in whom he perceives a systolic or presystolic murmur at the apex or base of the heart, and banish them to hospitals or health resorts? When advising a patient with a murmur and cardiac hypertrophy we first make inquiries as to the functional symptoms and the effects of exercise and work on the general condition of the patient. If we find that the field of cardiac response is limited, that work or any kind of exercise results in tachycardia, dyspnea, palpitation, pains in the chest, etc., the patient is put to bed and kept there till complete compensation is established, when we permit more or less activities again. The result is that the vast majority of our cardiac patients pursue their avocations; many with certain restrictions, to be sure, but only those who show signs and symptoms of temporary or permanent cardiac decompensation are urged to keep at more or less perfect rest.

For years it has been a mystery to me why we do not treat our phthisical patients in a similar manner. The only answer I could get was that the suburban sanatorium physicians who have applied the rest cure as a routine measure in all cases can no more conceive work or exercises for tuberculous patients. But we in the cities meet daily with individuals showing symptoms and signs of phthisis who keep at their work and support themselves and those dependent on them for years. And, strange

to say, they apparently last as long as those who have been induced to drop all work and have thus become burdens on their relatives or the community. In fact, in many of these tuberculous patients we observe that perfect rest for months is apt to be productive of considerable harm.

Prolonged rest of an individual or an organ has a deleterious effect on the muscular, and especially the nervous, system. This is drastically seen in limbs which have been kept in splints for some time. Because of disuse, the muscles atrophy, and subsequent attempts to use them meets with inhibition of response and aching or painful sensations. After a long rest in bed or on the reclining chair the patient is weak and unable to use his muscles. This weakness is often attributed to the tuberculous process, while in fact it is due to prolonged disuse of the muscles.

Idleness is also productive of neurasthenic or psychasthenic conditions. The patient becomes excessively introspective and constantly broods over slight symptoms. The advocates of indiscriminate rest for tuberculous patients forget that there is always a psychic aspect to every chronic disease, and they give their patients too much time to brood over the fact that they are invalids. In their intercourse with one another the patients exchange views as to present conditions and the outlook for the future, and their perspective, especially as regards prognosis, is rather limited. Several times a day the thermometrical readings are discussed; trifling gains or losses in weight are taken seriously, and, with the time at their disposal, they decide upon the prognostic significance of these conditions.

These are the main reasons why we find so many hypochondriacs among the sanatorium populations. Many are not at all amenable to reason. Especially is this true of those who have read considerable of the popular literature on tuberculosis which is so assiduously distributed by well meaning but ill advised individuals or societies. They come running to the doctor with the least change in their condition and in many cases are dissatisfied with the answers they receive and write to their favorite journal on tuberculosis for advice. A physician contemplating his patients suffering from nontuberculous diseases repeatedly asking for advice in the "question box" of a supposedly authoritative journal as to the significance of symptoms would be horror stricken. The thousands of patients with cardiac or renal diseases in this country, fortunately for them, have not been pestered with special literature, but many of the tuberculous patients who take the rest cure in and out of institutions are constantly given printed advice as to the significance of trifling or serious symptoms, the reliability of certain methods of treatment, etc.

Idleness is by no means a stimulant to the appetite, and those who, despite the idleness, consume sufficient quantities of food often become obese. The weak and the atrophied muscles are not benefitted by the adipose tissue, but remain flabby and unable to move freely, though the patients are thus often deceived, believing that they are improving because of the gain in weight. Prolonged rest is not at all a stimulant of the natural protective factors, as has been shown by Paterson and Inman. The patients are actually robbed of certain reactions which have been found of great benefit in counteracting the effects of the disease process.

Among well-to-do patients this mode of treatment often results in creating individuals who are living in institutions or in health resorts for life. In all the popular resorts we may meet with patients who have spent there five, ten and even more years, and they have no idea as to when they will be well enough to return home. Among the poor and dependents this method works even more havoc. The public sanatoriums at present retain their patients only for a certain period; some for six, some nine or, at most, twelve months. After this period the patients are discharged irrespective of their condition. If cured, they are told to go home and try some work, but almost invariably the admonition is given that indoor work is likely to produce a relapse, which is not true in most cases. In fact, nearly all are advised to change their occupations. But when the patients come home with the education they have received in the institutions, with their aptitude for introspection and careful analysis of the symptoms they may observe, especially those who are subscribers to one of the popular journals on tuberculosis, where they may ask questions and receive answers, they will never consider themselves fit for work.

Necessity for Individualization in Phthisiotherapy.—On the other hand, city practitioners who meet with many chest cases know of many tuberculous patients who keep more or less busy at their occupations and live as long as the average sanatorium patient. Similarly, the large contingent of tuberculous physicians on the staffs of sanatoriums all over the world do not indulge in the rest cure. While in many cases they demand it of their patients, they are working more or less hard; in fact, some tuberculous physicians have accomplished considerable and lived to the average age of medical men.

To be sure, phthisical individuals who are active in various human pursuits break down now and then. But patients subjected to the perfect rest cure have their ups and downs; acute and subacute exacerbations come at irregular intervals and pass away after proper treatment has been instituted. Any temperature or clinical chart of a sanatorium shows this undulating course of phthisis in a striking manner. Even hemoptysis, which is considered by some to result from exertion, has not been found more frequent nor more severe when it does occur in active and walking patients than in those at perfect rest.

Now, if many tuberculous patients in their homes can work, if nearly all the tuberculous physicians on the staffs of sanatoriums can be active at their avocation, if many of the numerous patients cared for in the tuberculosis clinics in our large cities can work and support themselves more or less, why cannot a large proportion of the sanatorium patients work? The fact that their mode of life is carefully regulated, their diet scientifically arranged, etc., should indeed be in favor of the vast majority of sanatorium patients doing their bit toward the care of the victims of the tubercle bacilli.

We have shown above that not all tuberculous patients are benefited by prolonged rest. But it

must be stated that many would be harmed if all were placed to work as a routine measure. Individualization is here imperative as it is in all therapeutic procedures. To be sure, it will add to the heavy burdens of the house staffs of the institutions, but it will undoubtedly bring heavy returns both to the individual patients and the communities which bear the ultimate burdens imposed by tuberculosis.

Which Tuberculous Patients Should Work?—In attempting to select the proper patients for work we should not be exclusively guided by the conventional "stage" of the disease, nor by the extent of the anatomical changes in the thoracic viscera. Some patients in the so-called "incipient" stage are not fit for any exertion, even though there are hardly any physical signs of a lesion to be discovered by exploration of the chest clinically or radiographically. On the other hand, many patients with extensive changes in the lungs or pleura, and even with excavations in the pulmonary parenchyma, are fit for some activities which may be quite remunerative. In the first class of cases just mentioned the constitutional symptoms are more or less severe. The patients have fever, tachycardia, dyspnea, and they emaciate rapidly. In the second class we meet with many who, though presenting signs of extensive involvement of the lungs, yet have lesions which are torpid, dormant or cicatrized. The cough is mild, though it may be productive; their appetite is good, they have no fever, no tachycardia, no dyspnea, and moderate exertion does not enhance the pulse and temperature. In other words, the instability of the pulse and temperature, characteristic of active phthisis, is lacking under ordinary conditions.

To determine these points we may be guided by the following observations:

The general appearance of the patient gives important hints in many cases. Those strikingly emaciated, with sunken cheek bones and hectic flush, are clearly not fit for any work or exertion; those with blanched mucous membranes of the eyelids and lips, indicating severe anemia, are in the same category, and so are all who show signs of objective dyspnea, or cyanosis of the lips and fingers. But it must always be remembered that slim individuals with tuberculous lesions are very frequently stronger and have a better outlook than those who are fat and puffy. The latter, as a rule, are very short-winded and weak, despite their external appearance of good nutrition.

As was already stated, the findings on physical exploration of the chest are not *per se* conclusive when attempting to solve our problem. I have many patients in this city who have cavities, unilateral or bilateral, who cough and expectorate sputum containing tubercle bacilli and still they keep on working for years. It has appeared to me that those in whom the main lesion is in the left lung are more disabled than those with the main lesions in the right lung. The former are more apt to suffer from severe dyspnea and cyanosis than the latter.

The most reliable criteria as to the ability to work are obtained by a study of the functional response of the body to exertion. This is best ascertained by a study of the effects of exertion on the temperature, pulse and respiration. In fact, all who advocate work for tuberculous patients emphasize that the thermometer is the most reliable guide as to the patient's fitness. But it has been my impression that a fraction of one degree F. is no danger signal in the average case. I know of many tuberculous patients who work despite slight rises of temperature some afternoons and they are not at all harmed by it. They keep on working for years.

It must be borne in mind that in these patients fever is not invariably due to tuberculous toxemia, nor to mixed infection. In many the rise is due to causes with which we are not acquainted, but which some are inclined to attribute to nervous instability. Indeed, any excitement, worry, grief, or anxiety may raise the temperature of a tuberculous patient. In some the temperature rises actually through fear or by autosuggestion. Especially is this true of those who have been in sanatoriums and who believe that they know all about the significance of thermometrical readings. For these hypochondriacs the taking of the temperature is an exciting event not lacking in suspense. The best to be done in these cases is to prohibit them from taking their temperature, or having it taken by somebody else without letting them know of the reading. If we succeed in convincing them that there is no significance in the slight rise in the temperature after exertion, the fever may in fact disappear.

Of even greater significance is the rate of the pulse. All patients with normal pulse rate may work more or less, while tachycardia is a distinct contraindication to activity. This is a fact which has not been appreciated to the extent it deserves. Indeed, it is exceedingly rare to meet with a tuberculous patient in whom the disease is active and progressive with a pulse rate under 75 per minute. Similarly, I have not seen a tuberculous patient with a slow pulse harmed by moderate work. Of course, in evaluating the pulse rate, the nervous element must always be borne in mind.

It should, however, be emphasized that patients in whom the lesion in the lung has cicatrized, but who remained with tachycardia, are permanently disabled, even though their temperature is normal or subnormal, which is not rare. It is well known that the pulse rate is less dependent on the extent of the lesion than on its activity.

Dyspnea is another contraindication to exercise and work. Some patients with healed lesions, with normal temperature, little or no cough and expectoration, remain short-winded for life owing to the interference with the pulmonary circulation, reduction in the extent of the pulmonary parenchyma, visceral displacement, etc. The patients may live long, but they will never be efficient at anything.

The psychic factor is of great importance. Among the city population practitioners frequently meet tuberculous patients who disregard all admonitions and keep at work till an acute exacerbation or complication compels them to take to the bed. At times we meet with some who keep on working for long years despite active disease. They are the paradoxes of practical medicine.

On the other hand, there are many in whom the disease is quiescent, or latent, in whom hardly any of the constitutional symptoms of phthisis can be

discovered, and they do not work. This class is mainly made up of ex-sanatorium patients. They are neurasthenic and psychasthenics; nothing will induce them to become active. They are under the impression that they know "all about TB," and the danger signals which they learned while in the institutions are never forgotten; in fact, they always imagine that they are in extreme danger. They are most difficult to handle. That it is not altogether quiescent or latent tuberculosis which is responsible for the psychasthenia is clear when we mention that even non-tuberculous patients, who have because of erroneous diagnosis spent some months in sanatoriums, are apt to display this fear for exertion.

Of course, complicating extra-pulmonary tuberculous lesions, e.g. of the larynx or intestines, or amyloidosis of the liver, spleen, intestines, etc., are contraindications to work, but patients with these complications are to be grouped with the progressive cases mentioned above. Those having pulmonary complications, such as thick pleura, bronchitis, pulmonary emphysema, cardiac dilatation, etc., are often only able to do light work, but even they are rather to be judged by the effects of exertion on the temperature, pulse and respiration than by the findings on physical exploration of the chest.

At the onset of the active stage of pulmonary tuberculosis work is apt to be harmful. The organism is apparently not yet adapted to the toxemia of phthisis as it becomes in chronic cases later on. These patients have fever, night-sweats, rapid pulse, are easily fatigued and sweat at the least exertion. They do best when put to bed for a few months till the fever abates and the pulse slows down and stays down after attempts at graduated walking exercises have been instituted. If these are well borne, and the temperature and pulse should be our main guides, they may be put to work. On the other hand, patients with old disease, immaterial at what "stage," in whom the lesions are circumscribed, and the pulse and temperature are normal, should work.

We may often be surprised how well they bear work, and in many we will find an improvement in their mental state. They become encouraged by the fact that work does them no harm, and with this encouragement we find also an increase in the natural resistance. The contrast is very striking when we compare them with patients with healed lesions, but who have been told by their medical advisers that they must abstain from work, work only outdoors, or change their occupations, which is often not feasible. The latter are often a discouraged and lazy lot, and take to bed at the least inconvenience. The experiences in most tuberculosis clinics in the large cities bear out these observations, though our suburban phthisiotherapeutists in the sanatoriums have had no opportunities to see such results, as a rule.

What Work Can Tuberculous Patients Do?—After the patients have been carefully selected as fit for work, there remains the problem what work should they be given. The answer to this question is different for patients treated in institutions and those treated at home. In both classes it is important to make the work simple because complicated systems of so-called "graduated labor," and the like, are as difficult of universal application as all other complex methods and are bound to fail, excepting in the hands of some enthusiast. It is also important to keep the patients at the sort of work to which they are used, *i. e.* at their own occupations, excepting when there are special and valid reasons against such a procedure. We are apt to forget that an individual's organism is usually adapted to his occupation by a process of either natural or artificial selection. Sociologists always bear this fact in mind, but physicians hardly ever do. After recovery it is best that the patient, with very few exceptions, should again engage in his occupation for which he is best fitted and at which he can make the best wages.

In institutions the patients who show but few of the constitutional symptoms of phthisis should make themselves useful; all whose pulse, temperature and respiration is around normal should work. The wards and grounds of the hospital should be kept in order by the patients; in fact, very little of outside, paid labor should be employed in public sanatoriums and hospitals for consumptives. With the present shortage of labor and, if the war lasts for some time, the depletion in the contributions to the funds for the maintenance of the institutions, this has become a real necessity. The beds, floors, windows, baths, lavatories, etc., of the sanatoriums should be kept in good order by the patients. A considerable part of the work in the kitchen is also suitable. It is unjust to the patients, as well as to the community, to employ paid labor for this work as is done in most American sanatoriums.

Patients who have been trained in certain specialized work, as well as skilled artisans, can make themselves useful while remaining in the sanatoriums. Thus carpenters, masons, house painters, plumbers, tinsmiths, electricians, etc., can do the repairs the buildings and their equipment may require. Others, who have been in the garment industry, as well as cobblers, can make themselves useful at their lines of work. The clerical work of the institutions can be done by clerks and stenographers who have been admitted as patients.

Patients treated at home should be encouraged to do some work, though it is more difficult to do so. Employers exact regular hours, and do not want workers who frequently miss days from the factory or shop. For this reason alone it is best that early cases of tuberculosis should be sent to sanatoriums where they may be given the rest cure till the active symptoms abate, when they may be tried out at work till found that they can stand it.

In this city we have a factory in which 75 tuberculous patients are employed. Most of them have been for variable periods in sanatoriums, but recently other patients have been admitted, and it has been found that they do well. In fact, some are admitted while they wait for vacant beds in the overcrowded sanatoriums, but finding that they are doing well, and earning money, they refuse to enter when they are called to the institutions. In this factory the simpler varieties of garments are made. Though many of the patients have not been employed at this trade before they got sick, and have to be trained, still their earnings are quite high. Working at piece work, they earn between $5 and $35 per week, the average being about $15 per week. Many of these tuberculous workers were

supported by charity societies before, and a considerable proportion feared work. But the education they have received in the factory—diametrically opposed to the teachings in the average sanatorium—has convinced them that they thrive on work, and this has had an excellent moral effect—they are spiritually encouraged by the fact that they can be self-supporting. It is not very flattering to the profession that this factory was conceived and elaborated by a mere layman who quietly and unostentatiously collects money for its support and spends considerable time in keeping it running. It may be stated that recently there is hardly any loss to the management—the factory is almost self-supporting. I shall, in the near future, publish a detailed report of the accomplishment of this factory.

It must be stated that numerous tuberculous patients are working and doing well, though we have no data as to exact conditions. When we bear in mind that hardly 5 per cent. of the tuberculous patients in this country are in institutions, while 95 per cent. are in their homes, it is clear that of the latter many are at work. The thousands of patients cared for in the tuberculosis clinics of our large cities are not all idle, and it is to be regretted that no detailed study has been made as to the condition of those who work as compared with those who do not.

Experience has, however, taught that the vast majority of carefully selected tuberculous patients will do well though working more or less. A certain proportion will now and then show symptoms of exacerbation of the active tuberculous process and they will have to be placed on the rest treatment for variable periods. But this should not discourage us. We know that patients under the perfect rest treatment have their acute and subacute exacerbations which are part and parcel of the undulating course of phthisis. It is clear that not all exacerbations are due to overactivity.

I have met with many patients with quiescent disease who felt quite well while working in the city, but during a period of rest when unemployed, or when taking a vacation, etc., acute or subacute exacerbations broke out which disabled them for some time. Many patients in sanatoriums who are not doing well under the rest treatment come to the city and promptly begin to improve, though they are quite active. The same is true of certain complications, especially hemoptysis, which is dreaded as much by physicians as by the patients. The idea that pulmonary hemorrhage is frequently due to overexertion has been exploded during recent years. Most cases, especially the copious and fatal forms of pulmonary hemorrhage, occur during the night, waking the patient up from his sleep. In institutions in which the rest cure is vigorously enforced the proportion of patients with hemoptysis is not lower than in others in which exercise and work are done by the patients.

It is important that the working patients should not be overburdened with rules and regulations as to indications and contraindications; it is not advisable to make them excessively introspective, which almost invariably leads to hypochondriasis. The average healthy person, if told that he must take his temperature, pulse, etc., every two hours to find out the effects of his task on his vital functions will surely break down. Indeed, this is the main objection to the so-called "graduated labor" about which so much has been written, but which has failed to gain a foothold in the vast majority of institutions, including its home, England.

With cooperating patients we may trust their subjective sense of fatigue as a reliable danger signal. When a patient reports that his task has engendered a sense of languor, has made him sweat unduly and he feels it difficult to continue, his temperature and pulse should be taken, and if these are found enhanced he should be placed at rest. In all who find work is not productive of a sense of fatigue the pulse and temperature should only be taken as routine measure two or three times a day. If these are found normal for several weeks, this also should be discontinued with a view of preventing the "temperature habit" which is responsible for many of the disabilities of many cured tuberculous patients.

In public institutions this method of placing patients to work can be used as the strongest argument to encourage them. When they realize that they have been selected for work because they have a better outlook for a speedy recovery, hardly any will shirk work, which is not the case now in most sanatoriums.

While this paper was being prepared I noted that an unusual number of patients under my care at the Montefiore Hospital asked for discharge. Inquiry brought out the following fact: Several weeks ago I discharged two patients and told them that they might go to work. After working for a few weeks they came visiting their friends in the hospital and told them that they were earning good wages and felt well. This acted as a stimulus to other patients who asked to be discharged so that they, too, might go out and work for the support of themselves and those dependent on them. In fact, it appears to me that in some institutions it may be advisable to pay the patients who can work and thus encourage them. If sanatoriums are institutions seeking to cure, educate, and rehabilitate tuberculous patients, the money thus spent will prove an excellent investment. Many patients may thus be convinced that they may work without harming themselves and leave the sanatoriums, making place for the numerous patients who suffer from active and progressive disease and are in real need of the kind of treatment available only in institutions, but are kept waiting for lack of vacant beds. It is obvious that the ultimate gainer will be the community charged with caring for its tuberculous patients.

Résumé.—Absolute rest is no more indicated in all cases of pulmonary tuberculosis than it is in all cases of organic heart disease. In both conditions, the effects of physical exertion on the functional capacity, and the constitutional symptoms are the only criteria as to indications for rest and work.

A large proportion of tuberculous patients showing signs of latent, inactive or quiescent disease, but who have nevertheless been admitted to sanatoriums, do not need absolute rest; in fact they may be harmed by it physically and psychically. They can and should work more or less, benefiting themselves as well as those who have to care for them. A considerable number of the sanatorium popula-

tions belong to this category. Work under proper supervision may help them toward a speedy recovery and prevent that form of laziness which is observed in many tuberculous patients after they are discharged from institutions.

In the individual patient the so-called stage of the disease, the extent of the lesion, the presence or absence of râles, etc., are not always safe criteria as to ability or fitness for work. We should be guided in most cases by an evaluation of the activity of the tuberculous process, manifesting itself in abnormal temperature, pulse and respiration. Just as a cardiac patient who does not become short-winded after exertion is permitted to continue at his avocation, so should a tuberculous patient be permitted, or even urged, to work if it is found that exertion does not increase his temperature, pulse and respiration.

That work will not invariably increase the patient's chances of acute exacerbation of the tuberculous process, nor shorten his life, is clear when we contemplate the large number of tuberculous physicians employed in sanatoriums. Although they work, some even quite hard, it has not been shown that they are more apt to be laid up by acute exacerbations, or that their average duration of life is shorter than that of other tuberculous patients.

With the present shortage of labor in this country it has been found difficult to run sanatoriums with hired labor. Institutions are therefore compelled to utilize most of their patients for the routine work, if they are to be managed properly. There is no doubt that it can be done, and now is the time to begin along these lines.

57 East Ninety-third Street.

TREATMENT OF CANCER AT THE ANUS.

By CHARLES J. DRUECK, M.D.,

CHICAGO.

PROFESSOR OF RECTAL DISEASES, CHICAGO HOSPITAL COLLEGE OF MEDICINE; SURGEON TO FORT DEARBORN HOSPITAL; RECTAL SURGEON TO PEOPLES HOSPITAL.

THE treatment of cancer of the rectum may best be considered from three points of observation, each presenting the disease in a different clinical picture: (1) Treatment of the precancerous conditions; (2) radical removal of the tumor (operative measures); (3) palliative or non-operative treatment.

Treatment of Precancerous Conditions.—We have as yet no definite knowledge as to the method of communication of cancer, but we know that in many cases there exists what may be called a precancerous state, when apparently benign growths are found. This condition is found not only in cancers about the rectum but also in malignant growths elsewhere; it may be diagnosed with certainty, and the patient given assurance that radical operation at this stage is effective, easy, and safe, and promises immunity from recurring, as opposed to certain death if the patient reaches us too late. Every patient complaining of local pains, with or without an abnormal discharge, should be carefully examined with the thought of possible cancer. Malignant growths at the anus or within the rectum should be removed at the earliest possible moment, but where the growth has involved surrounding organs radical removal is impossible, and tentative treatment to ameliorate suffering should be considered.

Surgical Treatment.—Extirpation of the rectum for malignant disease was first successfully performed by Lisfranc in 1826, and although his technique has suffered many changes the mortality from the operation is still very high. Tuttle says: "Extirpation is indicated when the growth is movable, and does not involve other organs; when no metastasis or ganglionic extension has occurred, when the patient's physical condition is such that he is able to withstand the shock of operation, and when marked cachexia is not present."

Preparation of the Patient.—In spite of very careful antiseptic preparation of the anal region, so many fatalities occur from infection and giving away of the sutures because of the flowing of the intestinal contents over the wound, that I always make an artificial inguinal anus as the first step. Whether this shall be a temporary or permanent inguinal anus depends upon the findings in the case.

One of the many advantages of colotomy as preliminary to excision of the cancer is the opportunity of examining thoroughly the bladder, urethra, prostate, uterus, and pelvis to determine if the disease has invaded structures other than the rectum. Sometimes adhesive bands from the rectum are only inflammatory, and if found to be so, extirpation of the growth offers hope of succcess. Involvement of the vaginal wall, bladder, or prostate betokens metastasis, and is a serious complication. When operative interference has been decided upon the patient should have a course of preparatory treatment to relieve toxemia and increase his resistance to infection. Such treatment very much increases his chances of recovery from the immediate effects of the operation. The patient's ability to resist infection is a large factor in prolonging his life. If the digestive functions remain good his physical strength is conserved and the constitutional invasion of the disease is retarded. Highly nutritious, absorbable foods, such as eggs, egg albumen, meat extracts, milk, and well-cooked cereals, are indicated, whereas sweets, uncooked starches, fibrous vegetables, and all foods that leave much intestinal refuse, should be avoided. Of course the patient's tastes will vary the diet list. The absolute milk diet is not so satisfactory as when meat, broths, and breads are allowed.

Irrigation.—Twice each day the rectum should be irrigated with one-half strength saturated solution of boric acid or 1 to 5,000 permanganate of potash solution to remove hard, lumpy, putrefying fecal masses, and also to relieve diarrhea or other discharges. The solution should run in slowly so that it will pass up above the disease, and thus wash out mucus, pus, and fecal matter which may have accumulated above or below the tumor. Under this treatment for two weeks sepsis is eliminated and the patient's physical condition much improved, and he is the better prepared to withstand the shock of operation.

The Perineal Operation.—The mortality from extirpation of the rectum by a perineal operation is much lower than that by any other method, but this type of operation is limited to epithelioma near the anus, and is not applicable where the cancer is in or above the rectum proper, leaving a

piece of healthy bowel below it at the anus. The immediate mortality of perineal extirpation of the rectum is due to infection which may occur during the operation from introducing the finger into the rectum and then into the wound, or by accidently cutting or tearing into the rectum, and thus allowing the intestinal contents to flow over the wound. Later infection occurs from the fecal discharges passing over the suture line. This latter danger may be avoided by providing the inguinal anus.

The anesthetized patient is placed in the exaggerated lithotomy position, with the hips well raised on sandbags. The rectum is well washed out with full-strength solution of hydrogen peroxide, followed by full-strength alcohol, and then plugged with gauze. Plugging the rectum protects against leakage, and facilitates its recognition during the later dissection.

A circular incision is made around the anus and deepened about one-half inch, separating the mucous membrane until the external sphincter is exposed thus dissecting off a tubular mass containing the anus, which is now securely closed by a stout silk purse-string ligature. A gauze wipe is tied over the anus with another strong silk ligature, which is left long for use as a tractor later. The external sphincter is next divided anteriorly, and the incision is carried nearly to the base of the scrotum, which is also divided posteriorly, the incision extending back to the tip of the coccyx.

The levator ani muscle is separated by blunt dissection with the scissors. The operator's hand is passed through this hole and the rectum, mesorectum, fatty tissue, and glands are carefully separated from the sacrum. The mesorectum may need to be freed from the rectum by snipping with scissors curved on the flat. The rectum is then freed from the levator ani on either side and the urethra and prostate in front. When the peritoneum is reached it can usually be worked up off the rectum, but if not it will be opened and gauze immediately packed in to prevent the small intestines prolapsing into the wound. The lateral supports of the rectum are fastened by two clamps and cut between, thus preventing bleeding from the middle hemorrhoidal artery. The rectum, being now freed, should come down easily. If it does not do so, the finger should be swept around the rectum and the binding attachments separated. Do not pull the rectum, for fear of tearing the mesentary and causing severe hemorrhage. The rectum is drawn out until healthy bowel is brought outside of the anus. The peritoneum is attached to the anterior intestinal wall by interrupted catgut sutures. The peritoneum must not be tightly drawn around the bowel, nor fastened with continuous sutures, lest subsequent stricture of the bowel result. The levator ani is sutured to the bowel carefully, closing with No. 1 chromic catgut the dead space in front of the bowel. The divided sphincter muscle is approximated to the bowel by sutures dipping down to the muscular wall of the gut, and the anterior and posterior cuts in the muscle are closed. The rectum is nicked across anteriorly to see that the mucosa is healthy and its blood supply sufficient, and if found satisfactory the incision is carried around the bowel. The mucosa must be picked up with snap forceps, and the bleeders sought especially at the mesentery. Gauze drains are placed in the anterior and posterior angles of the wound, the skin wound is closed, the mucous membrane is approximated at the new anus, a rectal tube is inserted, the patient's legs are extended, the buttocks are strapped together with adhesive plaster, and a large diaper of loose, fluffy gauze is held by a T-bandage. The gauze drains are removed at the end of forty-eight hours, and if there is no bleeding they are not replaced.

Complications of Extirpation of the Rectum.—Let us consider first the immediate mishaps, those occurring during the operation or convalescence, and liable to terminate fatally; then those that come on after the patient is about, which, while not directly causing his death, will seriously interfere with his comfort.

Injury to other pelvic organs may usually be avoided by a careful study of the anatomical relations of these organs, particularly the ureters and the bladder. The patient is usually septic, and enfeebled by toxicity from the accumulation of hard fecal matter above the neoplasm. This source of poisoning must be relieved by establishing an artificial anus before any effort is made at resecting the growth. After establishing this inguinal anus as a preliminary step to extirpation of the rectum, the distal segment of the bowel may be irrigated through and through for from a few days to two weeks, and thus rendered less septic. Then when the resection is performed there is no danger of soiling the operative field by escaping intestinal contents, and if stitches give away the wound is not bathed constantly in fecal matter as the bowel empties itself. The chief complication following extirpation of the rectum is sepsis, 75 per cent. of the deaths following this operation being the result of infection.

Hemorrhage is a serious handicap of perineal excision of the rectum, and when the patient is already weakened this considerable loss of blood may be a contraindication to operation. In the combined abdominoperineal method, where the peritoneum is closed at the end of the first stage of the operation, gauze compresses may be used as the perineal dissection progresses, and but a comparatively small amount of blood is lost. No vessels are tied until the rectum is completely dissected free and removed, because in the procedure the same artery will be cut several times, and much valuable time is lost if each "bleeder" is tied as it appears. The middle sacral, the right lateral sacral, and the two middle hemorrhoidal vessels are the ones usually needing attention.

Gangrene of the stump of the bowel which has been brought down and attached to the anus may result from (1) deficient blood supply, (2) too great tension in approximating the amputated bowel to the anus, thus tearing out the stitches, (3) discharge of feces over the wound. In this conjunction it is well to remember that arterioles which pulsate palpably when the bowel is retracted may be stretched too much for patency when the gut is dragged down. Therefore, I always look for a few small spurters in the severed bowel while attaching it to the anus.

Among the later complications following extirpation of the rectum, the most frequent is incontinence of feces, and many ingenious procedures have been devised for this unfortunate condition, but

without satisfactory result. In all of them incontinence returns after a period of time, and when the sphincter muscles have been removed with the neoplasm a permanent inguinal anus should always be established.

Stricture of the rectum of varying severity follows most amputations, and while it cannot be prevented it may be limited by beginning dilatation with bougies ten days after the operation, and later instructing the patient how to use them. Prolapse of the gut quite often follows extirpation, and may require treatment.

Palliative Treatment.—Palliative treatment is limited to inoperable cases, and comprises a number of measures to change distress into comfort and add months or years to the patient's life. Incurable cancer is by no means unrelievable cancer. Tuttle, speaking of his experience of twenty inguinal colotomies done for the relief of symptoms due to inoperable carcinoma, says he believes that in the large majority of inoperable cases just as much comfort and prolongation of life can be obtained by the persistent application of palliative methods of treatment. The essential of all treatment of inoperable cancer is to assist the patient to resist infection, and the maintenance of a good digestion is of prime importance. Predigested foods, milk, eggs, beef, lamb, chicken, meat extracts, and well-cooked cereals, are always indicated; but sweets, raw starches, and vegetables which leave much residue, are to be avoided.

Irrigation is especially indicated where there is much discharge, diarrhea, or constipation. In such cases the terribly repulsive odor of necrotic flesh drives the sufferer from his friends and makes him despondent. The ever-present odor also interferes with his enjoying his own meals. If this ulcerating rectum is irrigated twice daily, or even once only, but persistently, with a saturated solution of boric acid or 1-10,000 permanganate of potassium solution, a wonderful change is wrought. The odor disappears, septic absorption is stopped, and some patients actually put on weight. But the flushings must be continued uninterruptedly.

Drugs.—There are no drugs which in any way may affect the cancer. Digestants, tonics, and intestinal antiseptics all serve a good purpose in selected cases. Opium is contraindicated, as it produces hard, lumpy stools, which may cause obstruction of the bowel, or may tear away the bowel when passing the cancer, and cause severe hemorrhage. Unless opium is given in enormous doses it will not control the diarrhea. For the relief of pain, other sedatives may be given by mouth, or morphine hypodermically.

Curettage and Cauterization.—Sloughing surfaces surrounded by soft, pulpy masses often cause exhausting hemorrhages. If the growth is attached to the posterior wall, these soft bleeding masses may be curetted away with a Paquelin cautery (an ordinary sharp curette may be used, but I prefer the Paquelin). If the growth is situated upon the anterior wall this treatment must be used more advisedly, as there is danger of invading the bladder or peritoneum.

Radium and the *x*-ray are valuable therapeutic agents. By their use the growth may often be checked and the suffering of the patient relieved. In other instances they fail utterly, and their value is to-day quite uncertain. However, they should be considered in every case.

Conclusions.—To estimate the true value of surgery in cancer of the rectum we must know the object of the operation and its results.

The radical operation aims at removal of not only all the diseased tissues, but also those tissues which contain possibilities of future development. It is absurd to attempt extensive surgical procedure where the possibility of radical removal does not exist, and therefore the operation must be planned to suit the objects to be obtained. The age of the patient, his general health, strength, and the condition of his kidneys and cardiovascular system, must be considered.

The vital questions arising in the mind of every practitioner upon finding a cancer of the lower bowel is what course of treatment shall be advised, and why. Certain surgeons will not attempt extirpation unless the neoplasm is confined to the intestinal wall, movable, and not complicated by ganglionic or metastatic extension; others believe that adhesion of the rectum to other pelvic organs, and even the lymphatic enlargement, may sometimes be inflammatory, and a hope of cure may be expected in some of these. If the examining finger fairly passes beyond the growth in an upward direction the case may be considered favorable for operation. In the male, cancer of the rectum, close to the prostate, may not invade the prostate for a long time; in women, on the contrary, cancer on the anterior rectal wall soon implicates the vagina. If the growth is adherent to the upper part of the vagina the peritoneal membrane of Douglas's pouch is pretty sure to be involved, and the growth cannot be removed without opening the peritoneum. In such cases perineal resection should not be attempted, as the lymph glands beyond are doubtless diseased. If the neoplasm is confined to the posterior wall the case is much more favorable. There is no anatomical difficulty to a wide dissection. Glandular infiltration usually comes on later, and those in the hollow of the sacrum can be easily removed. A growth limited to the rectum, however high it may extend along the gut, may be removed by one of the various operations. Extension beyond the rectal wall, fixing it to the sacrum, bladder, prostate, urethra, vagina, or uterus, will usually constitute a contraindication to radical operation. The plan of procedure will vary with the patient. I divide my cases into three classes:

1. At the anus. (a) The sphincter may be preserved. (b) The diseased portion is removed and the proximal portion brought down and sutured to the skin at the anus.

2. Within the rectum or sigmoid. (a) The growth is removed. (b) The growth is short-circuited.

3. Neoplasms high in the sigmoid or in the colon. The growth, if removed, is resected extra abdominally, as advised by Tuttle in his three-step operation.

Perineal extirpation presents the lowest mortality, although it is the bloodiest method, and is often followed by an ulcerated area at the new anus. In doubtful cases the patient may choose the radical operation, with all its high mortality, in the hope of relief of symptoms and of prolongation of life, although the chances of permanent cure may seem slight.

Do not cut across a cancer and leave part behind. The part remaining will grow more rapidly than if you had let it alone altogether. An operation for cancer is an operation to save life. Cosmetic results are to be considered, but they are not to be weighed against recurrence and death a few years later. Never manipulate a cancer roughly, either before or during operation, or more often than is necessary to make a diagnosis. To do so is the easiest way to drive cells into lymph or blood current—hence metastasis. Do not rule out cancer because the patient is not old. About 10 per cent. of cancers occur before thirty-five. To save your patients from cancer, save them from delay. Do not wait for pain and cachexia—the signs of impending death. Be always on the watch for early suspicious symptoms. Be prompt to follow them to a definite diagnosis. Be courageous enough to insist on immediate proper treatment.

30 North Michigan Avenue.

SOME REASONS WHY HOSPITALS FOR THE INSANE ARE OVERCROWDED.*

By W. M. KENNA, M.D.,

MOUNT VERNON, N. Y.

A financial writer, discussing recently the question of money as it relates to human affairs, expresses the view that wars in the future may possibly be prevented by a restriction of the financial credit of any nation which shows a tendency to belligerency. His statement accentuates the perhaps sordid but nevertheless true fact that, getting down to essentials and eliminating romance, the financial side of most questions is the important one. And this element would seem to reach with its tentacular grasp even to the prosaic discharge of a patient from a hospital for the insane.

It has been the writer's observation that many of the laity are frankly of the opinion that in State hospitals for the insane there are patients held who are not deranged and who are thus unjustly retained in a state of incarceration. This impression is not narrowly confined, if one may judge from comments expressed here and there, and the reason for its wide distribution is not only obviously superficial in its causative relation, but is also easily explainable. It comes as the result of loose observation, the absence of critical analysis, the acceptance of hearsay testimony, and from a belief in the declarations of some of the unfortunate patients who, while lacking insight into their own deficient mental condition, yet apparently possess a logical and reasonable trend of mind.

Visitors to institutions for the insane frequently declare that they see nothing abnormal in many of the patients; that the latter seem to talk, act, and feel like normal people, and that it is difficult for them (as, truth to tell, it is sometimes difficult for the hospital attachés themselves) to differentiate in many of the wards between patients and attendants, if the latter are not clothed with distinctive dress or uniform. And so, because of superficial observation and by reason of the standard which is quite commonly held that either profound depression or active excitement specifically typifies the condition of insanity, the above opinion is formed, the necessity for intimate tests in determining an absence of mental abnormality not being appreciated. So far as their observations go, these critics are correct, but they do not delve deeply enough into the question and are not adequately trained to arrive at accurate deductions. And in their inner minds, even if they do not always openly express themselves, the feeling lurks that many of the supposedly insane patients are not in reality alienated. Hence the general suspicion which obtains.

It is strange, however, that people do not reason more intelligently as to the cause for this apparently unjust retention. It is only logical to assume that if these patients, presumably sane, are detained month after month there must be a motive or an ulterior object of some sort which acts as a basis for this detention. But nothing of this kind can possibly be visualized by any normal person if he considers the matter with fairness and without prejudice. The slightest reflection would show on its face that in any public institution of the kind under discussion a superintendent could have no real interest in holding a patient longer than was absolutely necessary. Almost every hospital is overcrowded; there is a crying need for additional buildings, and the trustees and superintendents everywhere are constantly harassed by the lack of sufficient accommodations for the patients already under their care. Surely something of a wholesale discharge would be welcomed with satisfaction by the heads of institutions and by their associated governing bodies. As most of the patients are usually in the pauper class, any insinuation that there is a thought of financial emolument in the minds of the medical officers would be bizarre as well as insulting. These existing conditions only serve to emphasize the ridiculousness as well as the unworthiness of these suspicions and false opinions. And it may be remarked here that this overcrowding which is so prevalent will naturally be increased rather than lessened as a result of the greater interest which is now being taken in the subject of insanity. For, as a logical effect of this greater attention which is being paid to the problem, a more careful scrutiny of deficient individuals is being made. A wave of concern is sweeping over the country in regard to defectives, and soon we may be in the anomalous situation of at once trying to relieve the congestion in our insane hospitals and at the same time of searching the community to uncover those below or different from an established standard.

But while it is true, and only quite natural, that the medical men of the hospitals are anxiously desirous of making as many discharges from them as possible and are constantly aiming at an ideal of 100 per cent. of recoveries among their patients, yet it can be truthfully said that in every hospital for the insane there are many unfortunates who are only slightly abnormal according to accepted standards. These are some of the individuals who seem to the superficial observer to be in normal mental health but who, to one accustomed to the analysis of insane people, present certain definite abnormalities of mental action; who show demonstrable irregularities in their ways of thinking,

*Read at a meeting of the New Haven Medical Society, May 3, 1917.

feeling and doing, and who evince a recognizable lack of capability to adjust themselves to their environment. It is the suitable disposition of this class which would go far to solve the problem of overcrowding as it exists today in every public institution for the insane and which, moreover, would help to disabuse the public generally of the ideas which it now entertains as to the unjust detention of many persons in these hospitals.

However, the difficulty which is confronted is that when the question arises as to the discharge of this type of patients there enters also the problem of responsibility. A superintendent of a hospital for the insane receives his appointment by virtue of his particular skill and knowledge and as a recognition of his ability in this field of medical science. Because of his experience and training he is presumed to know much of his subject and is expected by the exercise of the knowledge he has gleaned and the skill he has acquired to safeguard the interests of the community in which he lives.

Thus, upon the shoulders of a superintendent is placed a great responsibility in the matter of discharging patients committed to his care and supervision. The release of any individual becomes an affair of great potential importance not only to that person himself but to the outside world as well. Will a patient, upon obtaining his freedom, assault or perhaps murder some member of his family as the result of a concealed delusion? Will another, apparently free from his depressive anxieties and from his suicidal tendencies, slash his throat with a razor or throw himself into a neighboring lake at the first opportunity, even before the day is over? Will a third, although seemingly freed from his alcoholic propensities and although bodily fortified against the need for stimulation by his regularity of living and his improved general health, immediately abandon his resolutions and plunge into the depths of a spirituous debauch because he is unable to adapt himself to his new surroundings?

These are some of the questions which puzzle a medical officer whenever the matter of a patient's discharge comes up for decision. If a mentally sick patient does clear up and for a reasonable time presents a sane and normal attitude and can then be discharged with confidence as cured, there is always a feeling of justifiable pride and satisfaction on the part of the superintendent and his medical associates at the outcome. Thereafter, whatever the future may bring forth is purely a fulfillment of destiny. The hospital has done its duty, and its moral and legal responsibility ceases.

However, in the case of the merely improved patients—that is, of those who approach but who are unable to reach the level of the alienistic standard, a different situation presents itself. And just here arises, in a decided way, the question of responsibility, as has been said. The medical staff, in trying to determine the condition of the patient, must cast aside altruistic sentiments and then conscientiously endeavor, with the aid of their experience and teaching, to judge, as well as they are medically and scientifically able, whether or not a recovery has been effected. The patient's relatives or friends sometimes willingly leave the decision to those in charge and accept it as being final and infallible; and, indeed, they are often averse to the dismissal of the patient unless the medical officer will declare positively to them that a definite recovery has been accomplished. If this assurance cannot be given, there then ensues the probability of a hitch in the proceedings; and here is found, perhaps, one basis for the ideas inculcated in the minds of the laity to which allusion has been made.

In these cases an order from the court or the acceptance of responsibility by the selectmen of the town from which the patient is committed occasionally offers a solution of the problem in some communities. But again, such procedure is often held in check by the natural evasion of responsibility. The judge may wish the selectman to bear the burden, or the selectman may desire the backing of the court; they both may prefer to depend upon the superintendent's decision; and he in turn may wait for one of these functionaries to take the initiative. The judges and town officials are pretty generally unwilling to assume the responsibility. They themselves are amenable to the sway of public opinion, and whatever their personal altruistic or sentimental feelings may be, they naturally have a fearsome regard for the possibilities of the future, insofar as the conduct of the patient may involve them.

Habeas corpus proceedings are the bête noir of hospital superintendents; and it has seemed remarkable to the writer that these are so uniformly dreaded by the heads of hospitals. A writ of habeas corpus is the lawful resort of the patient and his friends if they favor a release against the judgment of the superintendent who counsels that the patient is not well enough to be discharged. One reason for this dread may be that such a court proceeding implies or seems to imply a reflection upon the superintendent's medical judgment, but one would think this process of law might more often be welcomed, for here would come a judicial determination of responsibility. If the patient were discharged, and if he caused trouble after his release, the onus would then fall directly upon the judge or jury who gave the decision determining the mental and legal status of the patient.

Paroles help somewhat to relieve the congestion. These are relatively rare, however, and, on the whole, because of their lack of finality, are not especially satisfactory. They do serve to render unnecessary the obtaining of new commitment papers in the event of a patient's not doing well and thus having to be returned to the hospital. It is possible that a lack of future financial provision for such patients may unconsciously act as a crucial deterrent in giving him a chance to be free and to associate with the outside world. That is to say, since most of the patients belong to the so-called pauper class and are pretty uniformly without financial resources, it may be that the fear for their future welfare and the distrust of their ability to adapt themselves to an environment of attrition both combine subconsciously to make for the detention of many of the mildly insane.

It does seem deplorable that most of the patients in hospitals for the insane must perforce upon their discharge take up the struggle for existence without financial backing and without freedom from monetary stress. Just the very ones who have

succumbed to the vicissitudes of life by reason of their instability are sent out again into the world in that condition so positively menacing to mental serenity—that of having a lack of money—and usually with no immediate prospect of employment which shall provide financial returns. The writer believes that many who are clamoring for the weeding out of the insane in these hospitals might quake with fear and apprehension if this same prospect confronted them under similar conditions.

There is a State Board of Charities in many states. This board has carte blanche in the matter of communicating with patients in the hospitals for the insane, and, as a corollary, the patients may appeal to the members of the board orally upon the occasions of the latters' visits to the hospitals, or at any time by writing to the board. Such letters are mailed with scrupulous care by the medical officers of the hospitals and are free from censorship of any kind. So it follows that the Board receives many letters containing pleas for discharge. Upon its tours of inspection the patients are interviewed privately and consideration is given to their requests. At the same time, the Board naturally respects the opinion of the superintendent, and his judgment is usually paramount. He is in a position to demonstrate an abnormality of mind if any exists, and he is properly qualified for such a demonstration. Mention is made of this Board to show that those inmates concerning whom there is a question as to their sanity or insanity have a friend at court, so to speak—a body which conscientiously and religiously acts as a moral check against possible indifference or unwise judgment. Thus the patients are given the opportunity of having their cases taken up for discussion in a proper and humane way by those who, while officially interested, are unprejudiced in every way.

The opportunities associated with the field workers and after-care systems relating to the future welfare of discharged patients are many and varied. These officials serve in a way as middlemen between the hospital authorities and the patients, and from the nature of their duties they are able to maintain with intelligent and personal interest a certain supervision over the patients and to guide with solicitous care the latters' efforts to maintain their mental equilibrium.

It is from these field workers and after-care corps of the state institutions that much is to be expected in time to come as a utilitarian measure of depletion. That is, provided they are clothed with suitable authority and with an elastic means of assisting the discharged patients financially, at least until they demonstrate their own capabilities for self-maintenance. It is not impossible that in future a fund expressly providing for the monetary contingencies of these discharged patients may be appropriated by our legislators as an economic resource aiming to relieve the large expense for building now necessary in caring for the insane under institutional supervision.

It is also possible that a boarding-out system may be a development of the future. If the maximum cost did not exceed the per capita expense of hospital care, there would be in reality a saving, for the elimination of some of the overhead charges and of the administrative outlay incident to hospital care would naturally ensue. Moreover, people might, under this system, take a more genuine interest in these unfortunates and look upon them less as being curiosities and with less of a fixed stare of detachment if remuneration were given for the trouble of caring for them. Such a plan would also help to limit the rapidly increasing and enormous demand for new buildings in which to house our mental defectives.

While it is extremely sad and unfortunate that so many of our population have to suffer incarceration in hospitals for the insane, yet it must be said that there is a lot of foolish and mawkish sentiment oftentimes expressed in regard to their condition of life. Generally speaking, the patients in these hospitals are well looked after, and many of them are serenely happy in their environment. The regularity of life, the opportunities and encouragements which are given to them for engaging in occupational diversion with incidental amusements and relaxations, the freedom from the social friction and irritation of the outside world and the absence of financial harassment all tend to make for mental and emotional poise and enjoyment even if the trend of their brains is appreciably abnormal.

After all, peace, happiness and contentment are coveted prizes in the battle of life, and for these we all strive. And surely even the prospect of a discharge from a hospital for the insane may not bring to a patient joy unalloyed if there is almost certain financial distress to be faced upon his return to his former environment with its attendant emotional, moral and mental strain.

7 Fletcher Avenue.

PELLAGRA:

ITS ETIOLOGY, SYMPTOMATOLOGY, AND TREATMENT.*

By J. F. YARBROUGH, M.D.,

COLUMBIA, ALA.

Much confusion abounds in the minds of physicians in regard to pellagra. The same conditions obtain in regard to many other diseases; notably, that of malarial hematuria. Most of this arises from the fact that authors do not make plain the type of the disease about which they write. The physician who treats a few cases of chronic malarial hematuria with quinine and mercury quickly reaches the conclusion that these drugs are harmful if not fatal in the treatment of the disease.

Another treats the acute type in the same manner and is impressed with their great value. This confusion is very noticeable in the treatment of pellagra. He who treats the chronic type affirms that the whole treatment may be summed up in two words, "peas and beans." The physician who treats the acute type is positive that the use of drugs, the transfusion of blood, and physiological salt solution are imperatively demanded.

If the confusion of types was removed I believe a common ground might be found upon which we all could stand. We have three distinct types of pellagra, viz., The acute, subacute, and chronic. In this paper I shall deal strictly with the acute and subacute types, with no reference whatever to the chronic.

*Read by invitation before the Georgia Tri-County Medical Association, at Arlington, March 17, 1917.

In the treament of any disease the physician must have an idea, right or wrong, of its etiology before the treatment can become anything more than an empirical procedure; therefore it is necessary to understand the author's idea of it before one can intelligently comprehend his method of treatment. In 1912 the writer announced to the profession through the Houston County Medical Society that the symptom-complex we call pellagra was an acidosis, the result of a carbohydrate or alcoholic diet in which there was practically no protein; therefore a poison and not a disease. I shall here introduce some facts in support of this etiology.

Sambon has probably done more research work in pellagra than any other man. In *La Presse Médicale*, December 18, 1916, he says: "Pellagra is a universal scourge which attacks all races and has millions of victims; which provokes crime, insanity, and suicide; and fills our prisons and asylums. Thierry claims the original focus to be in Austria in 1753. No one however believes that the disease is so recent in its origin. In fact I am almost certain that it is as old as civilization itself. The elder Pliny describes an affection which suggests pellagra, which prevailed in the localities which are most scourged at the present time." This seems to be strong evidence in support of our theory of its etiology. Note what Sambon says of the effect of pellagra, "It provokes crime, insanity, and suicide, and fills our prisons and asylums." Sociologists, criminologists, and thinkers generally all agree that alcohol is the most fruitful source of crime, insanity, and suicide. A striking similarity. Italy, the country most scourged by the disease, consumes more alcohol per capita than any nation in all the world. A fact pregnant with thought. Again, the universality of the disease strongly supports our contention, because there is no doubt that men everywhere since the days of Adam have transgressed the laws of dietetics.

The appearance of pellagra in the United States contemporaneously with the increased consumption of the carbohydrates, speaks volumes in support of our theory. One frequently hears a physician say: "We ate the same things fifty years ago we eat to-day, why did we not have pellagra then?" This query is based upon a false premise; the census reports show a very radical difference between the diet of fifty years ago and that of to-day. The increase in the consumption of sugar during the past decade has been more than five hundred per cent. In 1916 there was consumed a little less than 100 pounds per capita. The increase in the consumption of syrup has enormously exceeded that of sugar. The consumption of sweet potatoes has increased many hundred fold. Not many years ago they were grown in small patches, "scratched" early in the fall, and the supply was soon exhausted; to-day they are grown in great quantities, properly housed and canned, and are staple articles of diet the year round. There is more rice grown in America than ever before in its history. The cereal foods, practically all carbohydrates, are of recent origin. The increase in the consumption of soft drinks, as noted by the *Journal of the American Medical Association*, Jan. 27, 1917, is simply astounding. The retail value of this material in 1916 was more than $500,000,000. The National Ice Cream Manufacturers estimate their output for 1916 at 200,000,000 gallons. Add to the above that made by private manufacturers and in the home, and you have a bill against the United States well above the billion dollar mark for 1916. This material contains approximately an ounce and a third of sugar to each glass or saucer. You who are older remember when game, fish, squirrels, turkey, and deer, all rich in protein, were staple articles of diet; they are to-day practically unknown.

Many physicians have inquired why the Chinese are so singularly free from pellagra, living as they do almost wholly upon rice, a carbohydrate. These queries are based upon an erroneous premise. The Chinese do not live almost wholly upon rice. Fish enters largely into their diet. China has grown and consumed soy beans for more than 2000 years; to-day soy bean flour almost wholly supplants that of wheat in that country. Soy bean flour occupies this position in no other country in the world. Alcohol as a beverage is almost unknown in China, opium taking its place; another fact pregnant with meaning.

If the Goldberger experiment with the convicts in Mississippi in 1915 proved anything, it substantiated our theory of the etiology. Still stronger evidence is the results we obtain in the sanatorium; patients begin to improve the day the treatment begins; vomiting of weeks' duration subsides in 24 hours; diarrhea is never prolonged over 3 or 4 days; all symptoms begin at once to improve and the patient is dismissed, seemingly well, in 6 to 8 weeks.

I here and now challenge the profession to show such results from any other method of treatment, especially those who follow the teachings of Dr. Goldberger. If I were the only man who had had this experience, and it had been confined to a small number of patients, there would be room for doubt; but when we consider the fact that Dr. Decks had a similar experience, and that my patients now number more than 300, the results can be nothing less than the logical sequence of a rational treatment.

Symptoms.—The symptoms of pellagra are so familiar that a description of them is unnecessary; however, one feature of it demands our attention, because of its paramount importance. A large percentage of the cases show no dermatitis, and they may be easily overlooked, and disastrous consequences follow. Physicians generally are not recognizing this type of the disease; about one-third of our cases are of this character; in every one of them a negative diagnosis of pellagra had been made; their prompt recovery proved the error. No type of the disease is more difficult to treat; therefore, an early diagnosis is of the utmost importance.

Joe Wing, the greatest farm lecturer America ever produced, was a notable example of this character. This man suffered from "indigestion" for years; his real condition was overlooked, and a diagnosis of pellagra was not made until a short while before his death. A life sacrificed upon the altar of ignorance at the zenith of its usefulness. A red, sleek, or fissured tongue, indigestion, constipation or diarrhea, irritability or melancholia, with insomnia and persistent dreaming, are sufficient

symptoms to warrant a diagnosis of pellagra. The admirable paper read by Dr. M. L. Graves, read at the Atlanta meeting of the Southern Medical Association, very graphically described this anomalous condition.

Treatment.—If our acidosis theory is correct, we obviously have a perverted metabolism. Our duty would be: 1. To restore this function as quickly as possible by cutting off all material shown to be productive of the acid. The history of Deeks' patients as well as of mine proves conclusively that the carbohydrates are the offending material; therefore, all sweets and starches should be at once eliminated from the diet.

2. By increasing the alkalinity of the blood, rendering the acid already formed more easy of elimination. I have found no drug more dependable for this purpose than dilute nitric acid. (*a*) It renders the contents of the canal alkaline, affording quick relief to the crippled metabolism. (*b*) It renders the blood alkaline or neutral, quickly restoring its oxygen-carrying functions; the value of which is obvious to all thinking minds.

3. By aiding in every way in our power the eliminating processes of the body. If constipation is present, the bowels should be kept open with sulphate of magnesia. The eliminating function of the kidneys should receive careful attention, and be kept up to the maximum of efficiency. Usually the acid is sufficient for this purpose, however, at times the infusion of digitalis is of great value. The skin must receive attention, because it plays a very important rôle. Pellagrins rarely perspire: therefore the skin may be likened to a blanket of tar, completely cutting off one of Nature's most important avenues of elimination. Tub baths daily with gentle massage of the entire surface afford much relief. The transfusion of physiological salt solution is of great value here; it dilutes the poison, relaxes the tension, and in this way opens wide the emunctories.

4. By conserving and increasing the vitality of the patient by every known means at our command. If the intoxication is alarming, an immediate transfusion of blood should be given. If the symptoms are not so urgent, the transfusion of saline solution will be sufficient. These agents may be employed from time to time as required. The food should be daintily prepared and given in such quantities and at such intervals as not to overtax the digestive functions. The patient should be placed in a dark room thoroughly protected from the rays of the sun and all noise and excitement. The mental phenomena present a rich field for investigation. I said in my paper of 1912 that I believed this condition was the result of an alcoholic neurosis; I am now thoroughly convinced of the correctness of that diagnosis. This being true, the immediate elimination of all sweets and starches from the diet is imperative; the drugs best suited to the control of this condition are trional, veronal, and hyoscine. Mental therapeutics properly administered is one of our most potent weapons. The dermatitis requires no treatment other than cooling lotions and cleanliness.

At the suggestion of Dr. John Aulde, I have conducted a series of experiments with the chloride of calcium. In those cases of acute diarrhea with vomiting and abundant dermatitis this drug seems to be of no value; but in cases of severe constipation, with scanty secretions and but little or no dermatitis, the results are brilliant. The administration of the arsenical preparations, salvarsan and cacodylate of soda, so strongly advocated by Dr. Martin, and almost universally prescribed by physicians, is I believe worse than useless.

Many patients admitted to the Sanatorium in the last stage of the disease have taken large quantities of both drugs; like opium they mask the real condition, producing a sense of security from which the victim awakes in a more serious condition than before.

You will note that the treatment here advised is in conflict with the teachings of our government expert. Dr. Goldberger contends that the whole treatment may be summed up in one word "peas." I cannot believe, however, the doctor meant for us to take that statement seriously, merely a "confession of faith."

We have not dealt fairly by our patients unless day by day we impress upon them the fact that after recovery if they return to the carbohydrate diet, just so surely will they be poisoned again. Many physicians contend that this is proof positive that the patient had not recovered. This position is not tenable. If one is poisoned by mercury and recovers, and is later poisoned again, is it reasonable to contend that he had not recovered from the first poison? It is true that once having been poisoned by mercury the system is ever after more susceptible to the drug, but that is no proof that the person had not recovered. The same is true of pellagra; when once poisoned by the carbohydrates, the system becomes so sensitized to this material as to render it forever intolerable, no matter how thorough the recovery may have been.

To prove this theory, many experiments have been conducted upon former patients. The fact that I was once a pellagrin myself has afforded me ample opportunity to carry out these experiments on my own person, and to make an exhaustive study of this condition from a personal point of view; although I recovered years ago and am now in good health, the consumption of an ounce of sugar or syrup daily for a week will produce indigestion, a red tongue, and a sore mouth; all the other carbohydrates produce similar results at varying intervals of time.

The above theory of the etiology may be erroneous. I am open to conviction when sufficient proof is offered. However, there can be no error as to the value of this method of treatment, because our patients recover promptly, positively, and permanently.

Filiform Drainage in Puerperal Mastitis.—Dr. Di Sant' Agnese Valerio cured a severe case of this complication by the use of Chaput's filiform drainage.—*Il Policlinico.*

Dermographism and Syphilis.—According to Perntz 24 hours after an injection of succinimiotate of mercury positive dermographism can be obtained on subjects having primary and secondary syphilis as well as latent cases. It occurs with far more constancy than the Jarisch-Herxheimer reaction. — *Dermitologische Zeitschrift.*

HYPERTHYROIDISM.

By M. FORD MORRIS, JR., M.D.,
CHELSEA, MASS.
RESIDENT PHYSICIAN, SOLDIERS' HOME HOSPITAL.

SOME of the symptoms resulting from hypersecretion of the thyroid gland were first noticed in 1786 by Caleb Hillier Parry, a physician of Bath, England. Among the posthumous writings of Parry was found a description of eight cases of "Enlargement of the Thyroid Gland in Connection with Enlargement or Palpitation of the Heart." In the first one of these cases exophthalmos was also present. By Graves in 1830, and by Basedow in 1835, more detailed descriptions of the disease were given. At that time it was not known that excessive secretion of the thyroid gland was the cause of this malady. But since 1835 our knowledge of the symptoms, cause, and treatment of the condition often called either Parry's or Graves' or Basedow's disease has increased considerably.

Occurrence.—Hyperthroidism is a disease which affects women usually, Sattler's compilation showing that of the 3,800 cases 3,120 were females. Although a case in a suckling has been reported, this disease is uncommon in childhood. It is also interesting to note that familial occurrence is not at all infrequent, Frey having reported four cases in a family of five persons, and Ostereich having reported a family in which ten members were affected. Although the information is of no particular value clinically, this disease also occurs rarely in horses, dogs and cows.

Etiology.—Most of the symptoms have been produced experimentally by feeding large doses of thyroid gland substance. The symptoms thus produced were quite mild in comparison to those of a fully developed case of Grave's disease. Crile[1] believes that a hyperactivity of the suprarenal glands coexists with that of the thyroid, and states that "the symptoms of exophthalmic goiter are identical with those produced by the combined administration of epinephrin and of thyroid extract, plus the deterioration produced by the disease in certain organs." In summing up his discussion on etiology, Falta[2] draws the following conclusions: "Most of the symptoms can be referred to the hyperthryoidism; the cause of the hyperthyroidism is possibly conditioned centrally, and thus perhaps a series of symptoms and alterations in the function of other ductless glands are coordinate with the hyperthyroidism."

This disease frequently follows various infectious diseases, such as scarlet fever, acute articular rheumatism, etc. It frequently makes its appearance at the time of one of the sexual epochs—at puberty, during pregnancy, and at the menopause. Hyperthyroidism has a great reputation of beginning after mental shocks, such as fright, sorrow, and extreme disappointment. It also seems to affect more frequently persons in whom there is a neuropathic tendency or an instability of the nervous system.

This hypersecretion may occur in a gland previously normal, or one in an adenomatous condition. Obtaining similar results after feeding some tadpoles with normal thyroid tissue and others with adenomatous thyroid tissue, Graham[3] concluded that adenomatous thyroid tissue has the ability to functionate as does normal thyroid tissue. Important also is the fact that the symptoms of hyperthyroidism sometimes occur after the administration of iodine and medication with thyroid extract.

Morbid Anatomy and Pathology.—The two most characteristic postmortem findings are an enlargement of the thyroid gland and the *persistence* of the thymus gland. There is usually a uniform increase in the size of the thyroid. Early in the course of the disease the gland is soft and vascular, but in long-standing cases the thyroid loses much of its vascularity and becomes more firm. The iodine content is directly proportional to the amount of colloid present in the follicles, as much as 40 or 50 mg. having been found in one lobe. The iodine exists in the form of either iodothyrin or iodothyroglobulin. Microscopically there is an increase in the secreting tissues, which become branched or stellate instead of round or square, as normally they are, and the lining epithelium becomes cuboidal instead of cubical. Greenfield has called attention to the fact that the hypersecretory thyroid resembles the normal thyroid, as does the lactating mammary gland resemble the resting mammary. There is usually an abnormal amount of retrobulbar fat. There is often a hyperplasia of lymph structures around the thyroid gland.

Among the 36 autopsies done at St. Thomas' Hospital in London during the last 36 years, on patients who died of exophthalmic goiter, MacKenzie[4] reports the finding of a persistent thymus in 26 cases. According to Capelle's statistics, 44 per cent. of cases of hyperthroidism that died of intercurrent diseases had an enlarged thymus; 82 per cent. of cases that died of the thyrotoxicosis had an enlarged thymus; and almost 100 per cent. of cases of hyperthroidism that died at operation had an enlarged thymus.

Symptoms.—The number and severity of the symptoms are more or less dependent upon (1) the amount of hypersecretion, (2) the amount of this hypersecretion which is absorbed, (3) the ability of the organism to neutralize or detoxicate the excessive secretion, and (4) upon the stability or instability of the nervous system.

Cardiovascular Symptoms.—Probably the first, and one of the most distressing, symptoms is the tachycardia. The pulse rate varies between 90 and 200 per minute. The slightest exertion or the mildest mental shock will serve as a clutch to throw the cardiac mechanism into highest speed. Palpitation is often most distressing. There is an increase in the strength of the heart action; often also the area of cardiac dullness is increased, which increase is due more to dilatation than to hypertrophy.

The heart sounds are quite loud. Graves reported a case in which the heart sounds could be heard at a distance of three feet away from the anterior chest wall. At times, in the case of the writer's mother, these cardiac sounds were distinctly audible at a distance of two or three feet. Rather frequently there are systolic murmurs. In well-developed cases there is marked pulsation of the arteries in the thyroid gland and of the carotids; sometimes, in very severe cases, there is a pulsatory shaking of the head. Marked pulsation in the abdominal aorta, and in the liver and spleen has been observed.

It is, therefore, surprising to find a radial pulse

of poor tension and a normal or slightly subnormal blood pressure; but such is usually the case. This abnormal fall of pressure from center to periphery is explainable by the relaxation or dilatation of the peripheral vessels.

Falta attributes the tachycardia to irritation of the accelerator, and the peripheral relaxation to irritation of the vasodilator. Also he states that irritation of the root of the depressor nerve causes an increase in the blood pressure of thyroid gland vessels. Asher and Flack found that the excitability of the depressor nerve was increased by the internal secretion of the thyroid. The preceding statements help to explain the cause of the cardiovascular symptoms.

Glandular Symptoms.—More or less enlargement of the thyroid gland is demonstrable in practically all cases. The enlargement is bilateral in the great majority of cases. Rarely it is unilateral. The severity of the symptoms is by no means always directly proportional to the amount of enlargement, for slightly enlarged glands are often very toxic. On palpation a distinct thrill is felt; and on auscultation, vascular murmurs, synchronous with the heart's action, are audible.

Ocular Symptoms.—Bilateral exophthalmos is not uncommon; rarely it is unilateral, in which case the pupil of the protruding eye is dilated. This protrusion of the eyeballs is probably due to engorgement of the orbital blood vessels and to an abnormal relaxation of the musculus palpebralis. In long-standing cases the protrusion becomes permanent, due to the deposition of retrobulbar fat. A destructive keratitis sometimes follows the exophthalmos.

Retraction of the upper lid is frequent. The upper lid quite often fails to follow when the vision is turned slowly downward, allowing the white sclera to become visible at the upper border of the cornea (v. Gräfe's sign). Tremor of upper lid sometimes occurs. Involuntary winking is infrequent and incomplete. Möbius' symptom consists in a weakness of convergence. Suker has recently described another symptom under the term "deficient complementary fixation in lateral eye rotation." Kocher has observed that the rapid up-and-down movement of an object fixed by the eye causes a momentary convulsive contraction of upper lid. Joffroy's sign consists in the failure of the skin of the forehead to wrinkle when patient looks up.

Zentmayer[6] mentions the occurrence also of increased (rarely decreased) lacrimation, tremor of the eyeball, weak convergence, and paresis of the ocular muscles in the form of bilateral ophthalmoplegia externa, of the associated and of the individual muscles.

Nervous Symptoms.—One of the most common of all symptoms is a fine tremor of the separated fingers, which is usually not increased by voluntary motion, but which may disturb delicate coordinated movements. The tremor may affect the upper eyelids, lips, tongue, the arms, the legs, the diaphragm, and respiratory muscles, and even may seem to affect more or less the entire body, which last condition the French have termed "état de vibration perpetuelle." The tremor occurs eight to nine and one-half times per second. Cramps in the hands and feet occasionally occur during the night. "Drawing" pains in arms or legs or shoulders, and sometimes in entire body, beset the patients not infrequently. Muscular weakness, especially of the legs, is quite evident.

Mental Symptoms.—Abnormal irritability, great excitability, and strong emotion characterize this disease. There are often great changes in the moral nature. Insomnia is fairly common. The sleep may be unrefreshing, and productive of most unpleasant dreams. Somnambulism occasionally occurs. Infrequently, hallucinations or delusions of persecution beset the patient. Rarely insanity of the melancholic or the maniacal type supervenes.

Metabolic Symptoms.—An increased appetite and emaciation are a most frequent combination. Means and Aub[6] found that the general metabolism shows a characteristic rise in hyperthyroidism, which rise may be used as a functional test of thyroid activity or as an index of the intensity of thyroid intoxication. Dubois[7] found that the heat production in very severe cases was increased 75 per cent. or more above the normal average; in severe cases, 50 per cent. or more; in moderately severe cases, less than 50 per cent. "The fundamental exchange (or carbon dioxide production and the oxygen consumption in a fasting, quiet state) is increased. The protein exchange is increased also."[2]

Sattler has collected 40 cases in which hyperthyroidism and true diabetes occurred simultaneously. In these cases, however, it is very probable that an independent lesion of the insular apparatus of the pancreas was the cause of the diabetes. Nevertheless, in some cases, the hypersecretion of the thyroid serves to determine a glycosuric tendency, in which case the thyrogenic glycosuria improves with the amelioration of the symptoms of excessive thyroid secretion, and disappears with the cure of the hyperthyroidism. The elimination of phosphate may increase as much as 25 per cent.

Respiratory Symptoms.—Trousseau called attention to the soundlessness of the voice. Most observers have noted the dyspnea, which frequently amounts to 30 or 40 respirations per minute, and which is due to the increased need for oxygen. These patients often experience a sensation of scratching in the throat, as well as an irritating, persistent cough, accompanied at times by little expectoration and at other times by abundant sputum.

It is interesting to note that flushing and excessive sweating so often are present. The sweating explains the decreased electrical resistance of the body. In some cases the hairs of the head, the eyebrows, the eyelashes, as well as of the axillary and public regions, fall out. The appetite is capricious, both as to amount and kind of food. Excessive thirst is common. Vomiting and painless diarrhea sometimes occur, neither of which symptoms responds to treatment.

The blood often at first shows a slight leucopenia, and quite regularly a mononucleosis. In about 75 per cent. of cases the coagulation time is delayed. The urine is usually normal.

Hyperthyroidism does not seem to hinder or prevent conception, such patients often improving during pregnancy and usually going to full time. Irregularity of menstruation, amenorrhea, or menorrhagia, and leucorrhea are common.

Prognosis.—MacKenzie[8] summarizes the outcome of these patients in the following words: "The duration, the course, and the end of the disease in any individual case are uncertain. In about 25 per cent. of cases death results from the hyperthyroidism. In about 50 per cent. of cases more or less recovery will eventually take place. In the other 25 per cent. the disease continues in a chronic form during life." Following recovery from this disease, patients are rarely as strong and healthy as before. The outlook in children's cases is more favorable than in adult cases. Recurrences are not rare. Within the last few years the prognosis has become considerably better.

Treatment.—Absolute mental and physical rest is essential in all fully developed cases. A nurse who has had considerable experience in handling such cases is preferable. Encouragement has a good effect. Plenty of fresh air is beneficial. Alcohol and tobacco are harmful. Two tepid sponge baths or one warm tub bath, daily, are helpful. Tea and coffee are harmful.

It has been taught that a diet rich in protein should be given to offset the increased protein exchange which occurs in hyperthyroidism. Lately, however, the experiments of Falta go to show that administration of protein causes an increased thyroid secretion; and the experiments of Rudinger show that this increased protein exchange may be depressed to normal by the administration of an almost protein-free diet, but rich in carbohydrates.

Extracts of all the endocrine glands, alone or in combination, have been tried without benefit. It is almost unnecessary to state that the administration of thyroid extract or of iodine only aggravates the condition.

Various sera have been tried, without especial benefit. Beebe's serum, obtained from thyroidectomized animals, seems to be the best of that class of preparations.

Digitalis and strophanthus seem to have little or no effect upon the heart rate. The tincture of convallaria sometimes has a very beneficial effect on the tachycardia. Belladonna, in the form of the tincture or the extract, does good by decreasing excitability and restlessness. A capsule containing atropine sulphate, gr. 1/150, Squibb's extract of ergot gr. 5, and quinine hydrobromate gr. 5, given three times daily, produces good results.

Injections into the gland of boiling water have been tried without much improvement. But Watson[9] has reported securing very beneficial results in the relief of symptoms by injecting small amounts of a weak solution of quinine and urea deeply into the thyroid gland. Watson recommends this form of treatment for those cases not severe enough to justify surgical removal.

Aikens[10] reports his use of radium in the treatment of thyroid hypersecretion, and adds the histories of seven patients improved by the radiotherapy. This writer says that the effect of the radium is decreased vascularity and a reduced secretion.

X-ray treatment has given exceptionally good results. By using the Coolidge tube, the burning rays are screened and the penetrating rays are allowed to pass in. The strength of the ray is measured by a colorimeter. The dose should be just a little less than the erythema dose. The first effect of Röntgenotherapy is a slowing of the pulse rate, which is followed by a diminution of the nervousness and the disappearance of the tremor. Later, a gain in weight and a slight decrease in the size of the tumor occur. The exophthalmos is not much reduced. It is MacKenzie's opinion that a good way to handle these cases is to cause myxedema by means of the *x*-ray, and then relieve the myxedema by the administration of thyroid extract. Also irradiation of the suprarenals causes a marked improvement in hyperthyroidism.

The time required for a complete course of *x*-ray treatment varies from six to eighteen months.

The surgical treatment is also very important. In applying any surgical measures to these patients, the operator must remember the possibility of the patient's dying of fright, and should, therefore, use the greatest caution. In very severe cases the surgical work has to be done with the patient in bed, in which case the operating room is carried to the patient's room instead of the patient being carried to the operating room.

Some surgeons prefer local anesthesia, some choose ether by intratracheal insufflation, and others prefer a combination of the two methods.

At present, the removal of one lobe, the isthmus, and part of the other lobe of the thyroid, is the chief surgical procedure. The mortality in such operation, when done by skilled men, is less than 5 per cent.

The preferable treatment is to use first the medical and *x*-ray opportunities and to resort to surgery when those methods have failed.

VOMITING OF PREGNANCY.

By W. J. CAESAR, M.D.,

RICHMOND, CAL.

THE treatment of hyperemesis gravidarum must necessarily be based on the etiological factor involved. Reflex irritation and neurotic factors, however, should receive due consideration. The writer is not unmindful of the fact that vomiting of pregnancy as a neurosis is amenable to suggestive methods such as apply in the treatment of hysteria. Despite the recognition of the latter and the employment of a multitude of drugs, the induction of abortion or of premature labor not infrequently becomes mandatory.

The purpose of this contribution is to direct attention to one of the numerous reflexes discovered by Dr. Albert Abrams, of San Francisco, viz., the pylorus reflex, which is an insuperable aid in the treatment of the vomiting of pregnancy.

Relative to this reflex, the following is excerpted from the last edition, Vol. VII, of the "Reference

Handbook of the Medical Sciences": "Concussion of the fifth dorsal spine will dilate the pylorus. This fact has been utilized for the following purposes: 1. To relieve pylorospasm. 2. To facilitate rapid absorption and hasten the elimination of nauseous drugs from the stomach. 3. To eliminate the action of the gastric juice on drugs destined for action on the intestinal tract. 4. In the treatment of gastric affections. 5. To aid duodenal intubation—the ordinary stomach tube will pass directly into the duodenum during the time pressure is made at the fifth dorsal spine. After ingestion of the conventional bismuth meal, it takes approximately one hour and fifteen minutes for the stomach to void its contents, whereas, after stimulation of the fifth dorsal spine, the stomach voids the bismuth in one and one-half minutes."

Harley E. MacDonald, M. D. (Los Angeles) comments as follows: "Just as preventive medicine is abolishing the roller towel, broom and public drinking cup, so medicine is about to say farewell to the stomach tube. I believe that Abrams' pylorus reflex will revolutionize the practice of gastroenterology. I have already cured stomach troubles of many years' duration by instructing the patient to drink two glasses of water three or four hours after eating. Then to lie on the right side while a member of the family percusses the fifth dorsal spine. I recall a patient practically moribund from inanition superinduced by incontrollable vomiting and in whom ingestion of peptonized milk followed immediately by concussion of the fifth dorsal spine resulted in cure. It appears to me that we should worry no longer about the vomiting of pregnancy. —(*Physico-Clinical Medicine*, June, 1917.)

My experience with this simple maneuver embraces many cases which have proved refractory to the conventional methods of treatment. The method of execution is as follows: In the morning, before the pregnant woman rises, she ingests a glass of water containing sodium bicarbonate. Then she sits up in bed, and any member of the family is taught to strike a series of moderate blows (not in excess of one-half minute, to avoid exhaustion of the reflex) on the fifth dorsal spine, which has been located and marked by the physician. Any ordinary plexor and plexímeter suffice to execute these blows.

This preliminary maneuver is equivalent to stomach lavage. After resting several minutes until nausea, if present, is abated, nourishment is given and the fifth dorsal spine is again percussed. If, during the day, nausea or vomiting reappears and nourishment is rejected, the reflex may be elicited immediately after the ingestion of food.

It was indeed surprising for me to have achieved results by aid of this simple method which I first approached with so much doubt and uncertainty

---

Low Mortality Rate of Eclampsia in Scandinavian Countries.—According to Gammelhoft recent figures in Copenhagen give a mortality of less than 8 per cent. in 89 cases and in exactly 8 per cent. in 109 cases (rapid early delivery for severe cases, Stroganoff treatment for mild ones). A score of years ago the figures were much higher. A third obstetrician curettes the uterus after delivery and lost but three of his last thirty-four cases.—*Correspondenz-Blatt für Schweizer Aerzte.*

Medicolegal Notes.

Examination of Medical Experts and Defendants in Malpractice Case.—In an action for malpractice it appeared that the plaintiff had sustained a fracture of his left arm, the humerus being broken at the junction of the upper and middle thirds, the broken end of the bone being so separated and not in apposition that the musculospiral nerve was drawn in between said pieces of bone. It was alleged that he was treated by the defendants for nearly 8 weeks, when they abandoned the case; that his arm hung useless at his side and he was permanently crippled. Negligence was alleged (1) in failing to find out that the nerve was caught between the broken ends of the bone before bandaging the fracture on the first visit; (2) in leaving the nerve so caught; (3) in failing to bring the ends of bone into direct apposition with each other; (4) in applying a permanent dressing before they knew whether or not the nerve was caught. At the trial a medical expert had testified at great length and had been asked a lengthy hypothetical question, setting forth the facts claimed to have been shown. A question was then asked him as to how long it would take lymph to harden into bone in the case of a man such as the plaintiff, 61 years old and of previous good health, "as shown by the evidence in this case." It was held that this question was not improper as asking the witness to base his answer on all the evidence in the case, as the quoted phrase might fairly be interpreted as referring to the plaintiff's age and previous good health as shown by the evidence. The witness answered that it would take 4½ or 5 weeks, everything being equal. It was held that this answer was not prejudicial, as he had already testified without objection that the lymph would harden to the consistency of gristle in about 3 weeks in a young person or 5 weeks in an old person; this being substantially the same as his answer to the question objected to.

Questions asked the defendants as to whether they brought their best professional ability to bear upon the case and exercised their best skill, knowledge, and ability, and whether they exercised the utmost good faith, were held not leading or suggestive. Such questions did not call for the conclusion of the witnesses or invade the province of the jury, and should not have been excluded, as the witnesses were not asked whether they were negligent or exercised the care required of a physician. Judgment for the plaintiff was reversed and a new trial ordered.—Ingwersen vs. Carr & Brannon, Iowa Supreme Court, 164 N. W. 217.

Failure to Remove Sponge from Incision.—In an action for injury caused by the failure to remove a sponge from an incision after an operation for enlarged uterus, it was admitted by the defendant physician that the failure to remove any foreign substance from an incision is negligence *per se*, but it was urged that there is an exception to that rule in this: That it is not negligence for a surgeon to leave a foreign substance in a wound when in his professional judgment further exploration for such foreign substance would endanger the safety of the patient. It was therefore claimed that, the evidence showing that the patient was failing fast on the operating table, and that in the defendant's judgment it was necessary to sew up the wound at once in order to save her life, this case was brought within the exception. In Davis vs. Kerr, 239 Pa. 351, 86 Atl. 1007, and an Skike vs. Potter, 53 Neb. 28, 73 N. W. 295, the exception is recognized; but the court said that in both these cases it was based on the ground that either the surgeon relied on the count of the sponges kept by the nurses, or that he knew the foreign substance still remained in the patient's body, and in his judgment the patient's safety would be greatly endangered by any further exploration to discover and remove it. As there was no evidence in the present case that the sponges were counted by the attending nurses, or that the surgeon knew there was another sponge in the incision (he, in fact, testified that had he so known, he might have removed it), the facts in this case did not, it was held, bring it within the exception, conceding and approving for the sake of argument that such an exception exists.—Wynne vs. Harvey, Washington Supreme Court, 165 Pac. 67.

Military Medicine.

War Edema.—Under the name *das Kriegsödem* (war edema) great attention is being paid at present in the German medical journals to a peculiar disease which seems to have become widespread throughout Germany during the present year. The disease has broken out not only in numbers of the camps occupied by prisoners of war, but also in the large towns. Maase and Zondek (*Berl. klin. Woch.*, No. 36, September 3, 1917) give an account of the disease as they have seen it in Berlin. The first cases occurred in January, 1917; males above the age of 40 years have been almost exclusively the sufferers. No noteworthy premonitory symptoms were observed, but suddenly great edema developed, especially of the lower limbs. The face and scrotum were often affected also, and in a small number of instances ascites and hemothorax occurred. There were no cardiac symptoms, and the urine never contained any albumin. As soon as the patient was put to bed a very marked diuresis at once began, and the edema quickly disappeared. Remissions and recurrences were fairly common. The composition of the edema fluid in these cases had been compared chemically with the fluid effusions in renal disease and obstructive conditions such as hepatic cirrhosis. The chief difference found was the high ammonia figures in the Kriegsödem, as contrasted with the two other conditions. The pulse rate was markedly slowed during the disease, and examination of the blood gave, as a rule, a red count of three to four millions. This condition of anemia it was thought might probably be ascribed to hydremia. The occurrence of diarrhea was fairly common. The authors, in agreement with others, consider the cause of the disease to be underfeeding, especially the diminished quantity of fat. They suggest that toxic products of albuminoid metabolism may cause damage of the endothelial lining of the blood vessels, and so lead to edema. The high residual nitrogen and ammonia values found in the blood, urine, and edema fluids were considered to be evidence in favor of this hypothesis. By giving three patients 100 grams of fat daily for a week the authors were able to cure the disease completely without rest in bed or any other remedial measure. Another factor suggested as of etiological influence is the amount of fluid ingested. Owing to the changed food conditions most of the sufferers had been taking a more watery diet than normally in the shape of soups, turnips, and so on. The regulation treatment of the condition consists of rest in bed until all swelling has disappeared, diminution of the daily fluid intake, and bettering as far as possible of the diet. Schiff (*Muench. med. Woch.*, No. 22) states that the disease appeared in Vienna with great suddenness. He gives the usual pulse rate as from 42 to 56, and states that the amount of urine passed daily during the stage of recovery was commonly 3 to 4 litres. He suggests that this purely war disease has obvious similarities with beriberi and other diseases depending on failure of vitamines. Numerous authors have described the same disease as it occurs in the camps of prisoners of war, pointing out clearly its cause and the means that may be taken to remedy it when there is the will to do so.—*British Medical Journal*, October 27, 1917.

Value of Antitetanic Serum.—In an unsigned article in the *Archives Medicales Belges* for September, 1917, is an attempted revision of our knowledge of this subject. It has been possible to show by curves that the prophylactic value of the serum is beyond all doubt. Bruce's curve demonstrates that after November, 1914, when plenty of serum became available the morbidity dropped to almost zero and has remained at a very low average level. During September-October, 1914, before serum became available, the incidence of tetanus in the wounded was enormous. Attempts have been made, however, to show that a sudden large incidence or reduction in incidence could be due to other factors than absence or abundance of serum. Thus poor handling of the wounded soon after injury could be a factor, as could also a tetanigenic soil, and the presence of a large number of horses in the neighborhood. Against this kind of teaching is cited the experience with the disease at Kut-el-Amara. None of these collateral factors were in evidence when serum stamped it out. An equally suggestive experience was that of French and German wounded brought in side by side after a certain engagement. The German surgeon captured with his men declined the proffer of serum on the pretext that he did not regard it as efficacious. A number of German soldiers developed tetanus, while not a single French case developed. An entire series of such parallels is on record. Notwithstanding this kind of evidence there are skeptics. Thiéry divides the history of serotherapy into five periods, each of which appears to represent some modification of preceding opinions, or as Thiéry calls them, successive surrenders. The most recent of these takes account of the development of late tetanus and involves injections throughout the entire healing period of the wound. He anticipates further surrenders. This skeptical attitude appears to be attributable largely to frequent reports of "postseric" tetanus. These are due to certain foci of elaboration of tetanus toxin which are not reached by serotherapy any more than is the toxin which has become fixed to the nerve centers. From these foci of elaboration waves of toxin pass into the circulation. The majority of surgeons believe that these toxin waves can be reached by a barrage of repeated serum injections, but Thiéry seems skeptical. It is, of course, essential to make every attempt while dressing wounds to render closed foci of tetanus germs impossible and it is hardly fair to expect serum to neutralize incomplete disinfection of wounds. No doubt, serum or no serum, there would be a great difference in tetanus incidence in the wounded if one-half had their wounds scientifically treated, while in the other half haphazard methods were pursued. A subject of great importance in this connection is seroprophylaxis in second interventions. Here there is interjected the element of anaphylaxis. The more or less illusory danger from the latter is not to be contrasted with the danger of tetanus. The problem of anaphylaxis does not appear in connection with

frequently repeated injections but with the considerable interval which may exist between first and second operations it has to be borne in mind. In second interventions moderate doses of prophylactic serum are believed to be best. Of late, several injections have been condemned on the ground that the immunity which accrues is very short and shorter as injections are more frequently repeated.

The Professional Visual Acuity of the Soldier.—Ginestous writes at length in *Le Caducée* for September 15 of certain changes in the requirements for visual acuteness in the different kinds of army service. From 1894 to 1902 the superior limit of myopia was fixed at seven diopters. In 1905 it went up to 7, and in 1916 to 8 diopters. Up to 1902 there had been no provision made for the correction of astigmatism. Then correction with spherical convex lenses was recommended, while in 1905 correction with simple cylinders was introduced, and in 1916 spherocylindrical correction was employed. These reforms have made good in the services, but unfortunately they do not touch on the subject of acuteness of vision *per se*. In 1902 the requirements were that the good eye should have at least one-half and the poor eye one-tenth for the fighting man; while for the auxiliary the corresponding figures were one-quarter and one-tenth. In 1905 the vision for the poor eye need not exceed one-twentieth for the fighting soldier, while no fixed limits were established for the auxiliary. These figures have a purely physiological significance, or, in other words, a professional significance is ignored. Yet visual acuteness should stand in definite relationship to special needs. To become a soldier, certain general requirements must, of course, be satisfied, but aside from this those with superior vision should be utilized for certain activities in which such vision can be utilized. Thus far it is only the aviators who are required to have perfect vision. Binocular vision should be at least 1/5, 1/5, for ½ plus 1/20 is insufficient, in that a 1/20 eye is practically a blind eye, and binocular vision does not exist. Under such a condition 1/6 binocular vision rejects from the army, although ¼ monocular vision can be utilized in auxiliary work. In civil life three grades of visual acuteness are recognized: 1, ordinary vision; 2, superior vision; and 3, excellent vision. That is to say, there are three grades of occupation as based on the need of one or another degree of visual acuteness.

Hence the author would recommend the following scale for the army, so that every man's coefficient of vision could be properly utilized:

I. Excellent Vision. Under this head would be grouped aviators and gunners.

II. Superior Vision. Under this head would come men in all the services—infantry, cavalry and artillery, as well as policemen and firemen.

III. Ordinary Vision. Engineers, transportation men, munition men, artisans, laborers, hospital orderlies, etc.

IV. Inferior Vision. These men should have a definite relationship between their employment and eyesight.

War and Bacteriology.—Bacteriology is bound up in war, and therefore it may be concluded that the study of bacteriology will be given a great impetus by war. All phases of bacteriology have a more or less intimate relationship with war, but as that phase which concerns the prevention and cure of human infection is the one with which bacteriology and war come most closely into contact it will be briefly considered.

In the *Scientific Monthly* for November, 1917, Dr. David John Davis deals with this subject and points out that the ravages of disease germs in the army may not be the most serious part of the problem. The return of the troops to their homes must lead to a more general infection of the civil population with the various diseases that generally follow and are to a very large extent peculiar to military camps. Of these infections may be mentioned trench fever, infectious jaundice, trench nephritis, cerebrospinal fever, typhoid and para typhoid fevers, Asiatic cholera, and the dysenteries.

Typhoid and paratyphoid fevers need little comment, for vaccination and improved sanitary measures, have robbed them of their terrors and they seem to be no longer the scourge of armies in the field. Trench fever, which by the way, frequently attacks those who have never been in the trenches, first made its appearance on the Western Front and has occurred in Great Britain, Mesopotamia, the Balkans, Salonica and among the Austrian and German troops on the Eastern Front and in the Tyrol. The disease appears to differ from any hitherto known, it is a definite clinical entity and is doubtless of an infectious nature. While it is in itself not deadly, it causes a good deal of suffering and distress and interferes seriously with the efficiency of troops.

Trench nephritis has been a very frequent disease on all fronts, but the cause of the malady remains obscure. The specific microbe has not been isolated nor have attempts to transmit it been successful.

Cerebrospinal fever has been common during the war, in fact, it is essentially an army disease, affecting the men in barracks and camps, rather than those on active service. It seems to prevail especially in camps containing troops drawn from various parts of the country.

Infectious jaundice has been fairly frequent and is caused by a spirochete. The most interesting point with regard to this infection is that it has been shown that the germ commonly infects rats and consequently that trenches would furnish excellent facilities for the dissemination of the disease.

The dysenteries have been exceedingly prevalent in the armies engaged in the eastern and Mediterrancan campaigns and especially at Gallipoli. Emetine bismuth iodide, recommended by Dale and others and administered by the mouth has been found to destroy in the most satisfactory manner the pathogenic amebas.

Typhus fever transmitted by the body louse has been controlled by the extermination of this parasite.

Davis calls attention to the very important rôle that American bacteriology and hygiene have played in this war, which augurs well for the care of the American troops from the preventive and curative standpoints. Bacteriology has already effected much in controlling and stamping out disease, and undoubtedly the lessons learned from the war will advance the good work in this direction.

Red Cross Needs Dogs for War Work.—The Red Cross makes a plea for dogs to be sent to France with the Army Medical Corps. As was pointed out in a recent issue the dogs are used to scent out wounded men in places where Red Cross men cannot go, to carry medicine, food, and water to the wounded. They will also carry messages and dispatches when other means of communication fail. Thus far no legislation has been passed providing funds for the army to train dogs and the Red Cross has to train the dogs, maintain them, transport them to France, and maintain them in that country. It is estimated that there are now about 10,000 dogs serving with the armies. Dogs to be desirable should be between eight and ten months old, intelligent, loyal, and fearless. If dogs are found on trial to be unfit for service they are returned to their donors.

Laboratory Course for War Service.—Through the cooperation of the War Service Committee of the Medical Women's National Association, New York University, and the Bureau of Laboratories of the Department of Health, a course in medical laboratory work is offered to applicants who have a preliminary training in science obtained in a four-year college course or its equivalent. The object is to fit workers for war service in medical laboratories in this country and in Europe. The course will be extended over a period of three months and will require six hours' work each day. Applications may be made to Dr. Anna W. Williams, Research Laboratory, foot of East Sixteenth Street, New York.

Measles in the Army.—Reports of health conditions in the National Guard and National Army camps for the week ended November 9 show that measles and pneumonia predominate among the diseases which send men to the hospitals. The sick and injured rate in the National Guard camps was 33.9 per 1,000 and in the National Army camps 25.2. In the National Guard camps the Northern troops showed much more sickness of a communicable nature than the Southern troops. The same comparison prevailed in the National Army camps except at Fort Riley, which had nine cases of meningitis during the week. Camp Wheeler reported 34 new cases of pneumonia, and Camp Bowie 39. Camp Pike had 683 cases of measles and 76 of pneumonia. Camp Jackson reported 370 cases of measles. The measles cases are reported to be mild and the mortality from pneumonia low. The weekly health report of Camp Wadsworth contradicts the report of an epidemic which was in all probability the work of German propagandists, who are trying to cause alarm among people at home. Camp Wadsworth is said to be the healthiest camp in the history of the United States Army.

Medical Women in France.—The report that the American Women's Hospitals have sent a unit of women physicians to France is incorrect. These hospitals have sent through the Red Cross some twelve practitioners to France, who will work independently in various localities, but not as a unit. The organization of the American Women's Hospitals was inspired by the fact that the war service of the women of Great Britain is being made known to the world under the name of the "Scottish Women's Hospitals," and was established after consultation with the authorities in Washington. The work to be done by this organization differs somewhat from that of the Scottish Women's Hospitals in that the American women physicians will give civilian as well as military relief both in this country and abroad. The hope is that the American Women's Hospitals will be able to establish in the devastated portions of the Allies' countries a series of dispensaries to be tributary to central general hospitals. Those not needing hospital care may thus be looked after in the dispensaries, while the serious cases will be taken by ambulance to the nearest general hospital for treatment. The American Fund for French Wounded has officially suggested cooperation with the American Women's Hospitals, the latter to look after the diet and other factors relating to the rebuilding of health, and there are plans for cooperation with other relief organizations in other countries.

The Medical Officers' Training Comp at Fort Benjamin Harrison has been closed, and the medical officers who were still in training there have been transferred to Camp Greenleaf, at Fort Oglethorpe.

Surgical Dressings Needed.—Representatives of the Red Cross chapters of Southern New York State recently held a meeting in New York City for the purpose of stimulating war work. Dr. Allan McRossie, a member of a commission that spent some time in France, urged upon the delegates the necessity of keeping up the making of surgical dressings.

Major Grayson M. P. Murphy, head of the American Red Cross Commission to Europe, has gone to Rome to take charge of the administration of the relief funds sent to Italy until the arrival of the Permanent Italian Commission. Medicines, hospital supplies, food stuffs, and clothing have been shipped from various European warehouses to different points in Italy and in order to facilitate the movement of refugees free canteens and soup kitchens have been arranged for.

Hospital Interne Service.—The following resolution was adopted by the Public Health Committee of the New York Academy of Medicine on November 5:

Resolved, That the Public Health Committee of the New York Academy of Medicine suggest to the Surgeon General of the United States Army the desirability of a change in the wording of the "Circular of Information on the Completion of Interneships of Commissioned Officers (Form I—I)," permitting the period of interneship to terminate in December of the year following graduation instead of in July of that year. Permission to remain on the inactive list for the period named should, of course, be granted only "if the exigencies of the service permit."

Another Ambulance Fund for the American Army.—It seems to be the laudable ambition of every group of people, no matter for what purpose they have organized, to assist in supplying ambulances. A campaign has now been started among the billiard players of the United States to raise a $300,000 fund for the purchase of ambulances. One ambulance has already been purchased and will be on exhibit in New York City.

THE WAR AND HOSPITAL INTERNES.

THE war has called for many readjustments in the economic and social, as well as in other branches of the life of the country. It has deeply affected the medical profession and created a number of problems requiring solution consonant with the best interests of the country as a whole. One of the vital problems in this group is how best to serve the paramount needs of the military establishment of the nation without at the same time disintegrating the civil hospital service. When the first call for physicians was issued the profession responded loyally and patriotically. Many of the hospitals lost a large proportion of their attending staffs and internes. In the rush no consideration was given to any but military needs, and this was only natural and proper. As a result of the splendid response we now have a corps of medical officers sufficient for an army of almost two million men.

Before long we shall in all probability have a second call for physicians. Therefore, is not this the most opportune time to appraise the existing situation with a view of meeting the needs in a most efficient manner? Including homes for invalids and sanatoria of all kinds, we have in this country over three-quarters of a million hospital beds. A conservative estimate places the number of beds in general hospitals at 300,000. The total number of medical students graduating from our colleges is not much over 3,000 yearly. If all of them entered the general hospitals only, this would mean a ratio of one interne to 100 hospital beds. Until recently it was the general practice to require two years' service of the internes. This requirement doubled, as it were, the supply of internes and made for greater hospital efficiency as the interne's chief usefulness was in the second year of his service. The graded service, moreover, insured to the interne an amount of scientific grounding and experience indispensable to a competent medical practitioner.

When conscription into the army went into effect many of the internes and medical students were drafted. It took a great deal of protest and persuasion before the desired exemption was obtained. The army regulation as it stands at present exempts the forthcoming medical graduates from immediate service for one year following graduation in order that they may acquire hospital training as internes. The order reads that the exemption year shall end in July of the year following graduation, which usually takes place in June, although recently several medical schools, by utilizing the summer vacation period and by crowding the curriculum, will be able to graduate students at the end of the winter semester, in February. In view of this order granting but one year for hospital interneship, several hospitals have already abandoned, to the detriment of the institutions and their patients, the two-year graded service and introduced a one-year service. They did this reluctantly, simply to meet a war contingency. Others have procrastinated in changing the rule, particularly in view of the already serious depletion of the staffs of attending physicians and internes. They will, however, be compelled to do it if a change in the present ruling of the Surgeon General of the army is not effected. There should be no ineluctable difficulty in securing the highly desirable change in the present ruling in view of the fact that it can be rescinded at any time if the war requirement should demand it and in view of the further fact that, as has been suggested by the Public Health Committee of the New York Academy of Medicine (see page 901), it can be accomplished in a very simple way by changing the interpretation of the ruling fixing the exemption year. The Public Health Committee suggested in a recent resolution that the interne exemption year shall be interpreted as ending on December 31 of the year following graduation from a medical school instead of on July 31 of that year. By this change alone six months of additional service can be secured by the hospitals and if the students should be graduated in January or February instead of in June, an additional four or five months can be released.

It seems imperative that a change in the War Department ruling should be adopted, for it will not only benefit the hospitals of the country and end the existing chaos and shortage of help, but it will lead to a higher efficiency of the medical branch of the war service.

ANESTHESIA IN OBSTETRICS.

ONE of the many empiricisms in medicine which are rapidly melting away as a result of careful experimentation and thoughtful clinical observation is the long-held notion that in spite of the inherent danger of chloroform, it is nevertheless the best and safest anesthetic in obstetrical work. It was universally believed that for some unknown reason there was an especial tolerance to chloroform by the gravid woman, and a particular tolerance to it during labor pains. Those who feared chloroform ordinarily were quite reassured as to its safety in obstetrics. It is true that until such of the newer anesthetics came into general use as nitrous oxide, ethyl chloride, etc., chloroform was the most convenient anesthetic to use in the

short obstetrical manipulations and operations that arose during labor because of the simplicity of administration, small quantity of the anesthetic required, rapidity of full anesthesia, and rapidity of recovery therefrom without the discomfort and annoyances usually following on ether anesthesia. Fatality statistics were not collected and the real mortality from chloroform poisoning was not adequately brought to the attention of the practitioner.

Recent experimental work, described by Davis and Ferguson in a paper presented at the fifth annual meeting of the American Association of Anesthetists, shows that there are certain well-defined tissue changes which can in a measure account for sudden chloroform fatalities and the untoward effects of the other anesthetics. In animals narcosis with chloroform produced swelling of the cells, fat infiltration, necrosis, and hemorrhage. Ether did not produce necrosis, but there ensued a parenchymatous degeneration of a milder degree and some tissue swelling. On the other hand nitrous oxide had little tendency to cause tissue changes. In the profound tissue changes may be found a plausible explanation for the delayed fatalities from chloroform. But, of course, death from chloroform administration may occur at any stage and without premonitions of any kind as a result of ventricular fibrillation, which quite justifies the terror that this anesthetic usually has in general anesthesia. Indeed, statistics now at hand, even in obstetrical work, point to the fact that chloroform is the most dangerous of anesthetics. However, almost any anesthetic if administered over a long period will produce hemolysis, retention of metabolic products, and acidosis, especially in the fetus. And unfortunately in every consideration of the choice of an anesthetic or the effect of anesthesia too little, if any, attention has been paid to the effect upon the fetus. Yet in every case of untoward action the effect is more marked and more dangerous to the fetus than to the mother. This is especially the case with chloroform. In the case of nitrous oxide, considered the safest anesthestic, the long continued administration is very prone to produce asphyxiation in the fetus *in utero* even without visible effect on the mother. Of course, when there is cynanosis of the mother the danger to the child is very great, and while the administration of oxygen with the gas reduces this danger it does not wholly eliminate it in prolonged anesthesia, and rebreathing is so dangerous to the infant that it ought to have no place in obstetrical anesthesia. Aside from these contraindications in the use of nitrous oxide and its combinations, high blood pressure, especially that encountered in the preeclamptic stage, and hyperthyroidism are absolute contraindications to its use.

It seems then that ether is still the safest anesthetic to use in obstetrics if there do not exist any contraindications such as would bar it in general surgery, as long preanesthesia period—that is, the long first stage—after-effects, complications, etc. Ether is borne better by both fetus and mother. Of course, both ether and chloroform tend to lessen contractions of the uterus, are cumulative in their action, and are not so quickly eliminated. To a much greater degree than with chloroform babies born after ether anesthesia may show the effects of the drug for many hours. Except for the marked tendency to asphyxiation nitrous oxide does not have any after-effects on the infant because of its rapid elimination.

THE FOOD QUESTION.

THE problem of conserving the nation's food supply is one of the most vital importance in the prosecution of the great struggle in which this country is now engaged. Not only do we have to feed our own people at home and our armies abroad, but also do we have to export tremendous quantities of foodstuffs to our allies in order that their civil as well as military population may be adequately nourished. This is a gigantic task which cannot be accomplished unless our food administrators have the entire cooperation of all members of the community. Aside from the immediate need of minimizing the great wastage of food that is without doubt one of our besetting national sins, it is imperative to increase production and reduce our consumption of certain foods, especially meat, wheat products, and sugar. This calls for the exercise of the utmost care in selecting dietaries. It is beyond dispute that many people eat more food than is actually required for their proper maintenance in good health and strength. This can be attributed chiefly to the habit of self-indulgence and the desire to "tickle the palate" with some delectable dish. The Epicurean tastes developed by a not inconsiderable part of our population, *pari passu* with the phenomenal prosperity that this country has enjoyed during the last two years, probably accounts for some of the evils from which we are now suffering.

The excessive ingestion of food leads to an overtaxing of the organs of elimination with resultant injury to the system as a whole from the accumulation of deleterious waste products. It is a well known fact that a continued high protein intake is a prolific source of arterial degeneration and that bugbear of modern American life—high blood pressure. From the standpoint of individual and collective health, therefore, a restriction in the amount of protein consumed would not only make for greater efficiency, but would also lessen the tendency to many of the ills which can now be ascribed to overeating.

The experiments of physiological chemists have shown that an averaged-sized adult can get along comfortably on 118 grams of protein, 500 grams of carbohydrate, and 50 grams of fat a day, which dietary yields approximately 3,000 calories. This is considered a "standard" diet and can of course be modified to suit the climate, the amount and

character of manual work, as well as the individual's appetite and purse. In order to conserve the meat and wheat supply as much as possible, substitutes have been suggested, such as fish, vegetable and nut proteins, milk, eggs, corn products, etc. It is not a difficult task to arrange a palatable and nutritious menu with the aid of scientific data in regard to such matters so readily accessible. Lusk in his book on *The Science of Nutrition* puts the problem very succinctly when he says that impending food shortage can be remedied by increasing the number of milch cows and by reducing the live stock raised for meat. The latter would free arable land for the production of grain and potatoes and save for human consumption grain fed to steers. It is quite certain that meat in the quantity it is consumed to-day is entirely unnecessary, and it is susceptible of scientific proof that mechanical work is more efficiently and economically derived from carbohydrate food than from meat.

VITAMINES IN THE SOLDIERS' RATIONS.

Dieticians are rather conservative in taking up the subject of vitamines, just as they were formerly in the adoption of calories. This means, of course, that they are slow in explaining certain effects by the presence or absence of vitamines, although they fully recognize, and indeed are the first to insist upon the necessity of certain food articles for the prevention and cure of deficiency diseases. The old theory that certain mineral ingredients and vegetable acids prevent deficiency diseases will probably die hard and, as a matter of fact, in the installation of vitamines as dietetic necessities we may go to the extreme of overlooking the role of the substances above mentioned on nutrition. It is highly important that the two factors—inorganic matter and vitamines—be kept quite distinct in connection with dietetics. In the classic experiments in mineral starvation were vitaminiferous substances also absent from the diet?

The subject of vitamine defect in soldiers' rations has come to light in Italy, in which country it was announced last May by Ramoino (abstract in *El Siglo Medico* for September 1) that the soldiers on the fighting line and in the trenches were suffering for lack of certain elements of nutrition. The symptoms which presented themselves were gastroenteric disorders, nocturnal diarrhea followed by constipation, various eruptions, epistaxis, cyanotic gums, and oral fetor. There were also headache and pains in the muscles and joints and some subjects showed edema. Loss of weight, sluggishness, and melancholia were present to some extent. The ration contained sufficient calories for hard work and sufficient protein, but the above mentioned complex of symptoms did not begin to disappear until vegetables and fruits had been introduced into the dietary. It was evident that antiscorbutic vitamines had not been represented in the ration. Pains had been taken to prevent beriberi by leaving certain vitamines in the diet and nothing resembling this affection developed. It is well to remember that scurvy largely disappeared from Europe when the potato cultivation was introduced from America. Lemons should be readily available for Italian troops.

Uniting Wounds Without Suture.

More than one hundred years ago the expediency of bringing all wounds together by stitching was questioned. As Dr. Douglas H. Stewart has pointed out in the *Western Medical Times* for August, 1917, Samuel Cooper, a well known British army surgeon, in the year 1807 recommended the conjoined operation of position, of adhesive plaster, and of a bandage for the uniting of certain wounds, in place of sutures. This old writer described the type of wounds suitable for this kind of treatment and the manner of bandage to be employed. It is interesting to note that a nurse who does a good deal of bandaging for Dr. Stewart is an enthusiast for Cooper's bandage as a substitute for the usual strapping of varicose veins and ulcers. Stewart himself has applied such bandages not only to the kind of wounds described by the original exponent of the method, that is to longitudinal wounds, but to transverse ones as well, and is very favorably impressed with this principle of wound treatment. It certainly seems reasonable to believe that suturing of wounds should not be practised when these can be united as quickly and as well by bandaging or strapping.

News of the Week.

Relief for Italy.—The American Red Cross has doubled its contribution for the relief of Italian refugees. Ambassador Page had already been instructed to draw on the Red Cross for any amount up to $250,000 for relief work in Italy. On November 11 another $250,000 was appropriated to meet emergencies arising in consequence of the recent reverses of the Italian army.

Plan Relief for Jewish War Sufferers.—Plans have been laid by the Jewish Board for Welfare Work in the United States for conducting a campaign to raise $5,000,000 for the relief of Jewish war sufferers. The campaign is to be carried on during the two weeks beginning December 3. The Jewish War Relief Fund for 1917, when the New York campaign is finished, will amount to $10,000,000.

The Adirondack Cottage Sanitarium is to receive one-half of the residuary estate of Robert W. Patterson, amounting to upward of $1,000,000.

Cooperative Plan to Further Clinical Study.—Officials and instructors of medical schools and colleges and representatives of the staffs of the various city hospitals met at the invitation of Deputy Commissioner H. C. Wright of the Department of Public Charities with the Society of Medical Jurisprudence, at the New York Academy of Medicine, on November 12, to listen to a discussion of "The Municipality's Relation to Medical Education." It was brought out that the hospitals operated by the

city have more than 16,000 free beds, and that not more than one-fifth of the cases treated were considered for clinical or other educational purposes by post-graduate students. The suggestion was made that there be some unity of plan between the medical schools and the city hospitals whereby this immense amount of clinical material may be made available for study. The announcement was made that plans had been approved by Commissioner Kingsbury for systematic courses of medical college instruction in the City Hospital and the Institution for Feeble-Minded on Randall's Island which will be opened the first of the year.

Venereal Diseases to be Reported in Philadelphia.—Representatives of the Departments of Health and Charities of the city of Philadelphia met on November 12 to discuss the advisability of making the so-called social diseases reportable. It was the consensus of opinion of those present that the proposed plan should be put into effect. The Health Department will take steps to make these diseases reportable in the near future.

Regulations Affecting Sale of Medicinal Alcohol.—The office of the Commissioner of Internal Revenue has announced a decision which permits pharmacists to sell small quantities of non-beverage alcohol without a physician's prescription to persons who do not hold a permit. The quantity must not exceed a pint and it must first be medicated in accordance with one of the following formulæ: 1. Carbolic acid 1 part, alcohol 99 parts. 2. Formaldehyde 1 part, alcohol 250 parts. 3. Bichloride of mercury, 1 part, alcohol 2,000 parts. 4. Bichloride of mercury 0.8 gram, hydrochloric acid 60 c.c., alcohol 640 s. c. c., water 300 c.c. 5. Bichloride of mercury 1½ grains, hydrochloric acid 2 drams, alcohol 4 ounces. 6. Formaldehyde 2 parts, glycerine 2 parts, alcohol 96 parts. 7. Carbolic acid 1 dram, tannic acid 1 dram, alcohol 1 pint, water 1 pint. 8. Alum ½ ounce, formaldehyde 2 drams, camphor 1 ounce, alcohol and water, each 1 pint. 9. Lysol 1 part, alcohol 99 parts. 10. Liquor cresolis, comp. 10 c.c., alcohol 1,000 c.c.. The container of such alcohol will bear a "poison" label. Any abuse of these privileges will result in recall of the pharmacist's permit and its cancellation.

Memorial Services for Dr. Lewis A. Stimson.—On the afternoon of November 16 exercises in memory of Dr. Lewis Atterbury Stimson, formerly professor of surgery of the Cornell University Medical College, were held in the college auditorium. Addresses were made by Dr. Jacob Gould Shurman, Elihu Root, Dr. W. Gilman Thompson, Dr. Edward L. Keyes, and Howard Townsend of the Board of Governors of New York Hospital.

Dr. Thomas F. Reilly has been appointed to the Chair of Medicine in Fordham University School of Medicine.

Dr. Evander M. Sanders of Nashville has been appointed president of the State Board of Health of Tennessee to succeed Dr. R. E. Fort. Dr. W. J. Miller of Johnson City has been elevced vice-president.

The Southern Illinois Medical Society, at its forty-third annual meeting, held at Duquoin, Ill., elected the following officers: *President,* Dr. E. C. Alvis of Benton; *First Vice-President,* Dr. H. H. Roth of Murphysboro; *Second Vice-President,* Dr. Max Adles of Duquoin; *Secretary-Treasurer,* Dr. A. B. Capell of Shawneetown; *Assistant Secretary,* Dr. C. W. Lillie of East St. Louis.

The Kentucky State Medical Association, at its annual meeting, held in Louisville, on November 8 and 9, elected the following officers: *President,* Dr. J. S. Lock of Barbourville; *First Vice-President,* Dr. J. L. Barker of Pembroke; *Second Vice-President,* Dr. H. H. Stallard of Pikeville; *Third Vice-President,* Dr. J. C. Douglas of Franklin; *Delegates to the American Medical Association,* Dr. W. W. Richmond of Clinton and Dr. C. L. Wheeler of Lexington.

Harvey Society Lecture.—The third lecture of the present course will be delivered at the New York Academy of Medicine on November 24, 1917, when Dr. Linsly R. Williams will speak on "The Medical Problems of the War."

United States Civil Service announces an examination for the position of pathologist, for men only, on December 5, 1917, to fill a vacancy in Freedman's Hospital, Washington, D. C., at $2,000 a year. Future vacancies requiring similar qualifications will be filled from this list. Applicants should apply for Form 1312 and for further information to the Civil Service Commission, Washington, D. C.

The Commission also announces an open competitive examination for medical interne, on December 5, 1917, to fill a vacancy in St. Elizabeth's Hospital, Washington, D. C., at $900 a year. Future vacancies requiring similar qualifications will be filled from this list. Applicants desiring to take this examination should apply at once for Form 1312, stating the title of the examination desired to the Civil Service Commission, Washington, D. C.

Examination for Medical Inspector.—The Municipal Civil Service Commission of New York announces an examination for Medical Inspector, Grade 1, male and female, for which applications will be received at Room 1400, Municipal Building, until November 20, at 4 P. M. The incumbents of these positions in the Department of Health may be called to the examination of infants, or school children, to make the diagnosis of communicable disease, to engage in the diagnosis of tuberculosis, syphilis, and the various occupational diseases, and to investigate, report, or correct, conditions unfavorable to the health of individuals or communities. The salary range of Grade 1 is to, but not including, $1200 per annum for part time service, not less than 18 hours weekly.

Tuberculosis and the War.—Kerr, in a memorandum entitled, "The Influence of War Conditions Upon the Death Rate from Consumption," states that his own city, Newcastle-upon-Tyne, shows an increase in the number of deaths from tuberculosis since the outbreak of the war. He finds a similar increase in other parts of Great Britain, but a much greater increase in those countries whose territory has suffered most. Among the conditions which are specially liable to render people susceptible to tuberculosis he gives poverty the first place, either actual or relative to the rising cost of food; next he places insufficient housing and overstrain, either physical or mental. He says that practically the whole civil population is suffering from overwork

or anxiety of mind. He finds a considerable increase in the number of deaths from tuberculosis among that section of the population which has been especially affected by the new conditions of life brought about by the war, namely girls between the ages of fifteen and twenty years who have filled the gaps in factory, shop, and office, and even in the heavier outdoor employments. It is in this group of young women that the great rise in the death rate from consumption occurs.

A New Antisyphilitic.—At a meeting of the National Academy of Science in Philadelphia on November 20, Dr. Simon Flexner announced the discovery of a new arsenical preparation for the treatment of syphilis. The new drug, called A-189, is said to be superior to salvarsan, being parasitotropic to a much higher degree.

The Nevada State Medical Association, which met in Reno, Nev., on October 22, elected the following officers: *President,* Dr. H. A. Brown of Reno; *Secretary-Treasurer,* Dr. J. L. Robinson; *Delegate to the House of Delegates of the American Medical Association,* Dr. William Z. Dahl of Reno.

Obituary Notes.—Dr. Margaret Abigail Cleaves of New York died in Mobile, Ala., on November 13. She was a graduate of the University of Iowa Medical Department, in 1873, and a member of the American Electro-Therapeutic Association. She was formerly superintendent of the State Insane Asylum at Mount Pleasant, Iowa, and later superintendent of the State Insane Asylum at Harrisburg, Pa. Dr. Cleaves was the author of a work on electrotherapeutics and of numerous contributions to the literature on this subject.

Dr. Simeon Cole Bradley, a graduate of the College of Physicians and Surgeons, New York, in 1880, died suddenly of heart disease at his home in Nyack, N. Y., on November 13, aged 63 years.

Dr. Arthur Martin Clapp of Springfield, Mass., was electrocuted by a high power electrical machine with which he was experimenting in his office, on October 31. He was a graduate of Harvard Medical School, in 1902, and was 41 years of age.

Dr. Edward Johnson, a retired physician, formerly of Fullerton, Neb., died in an Omaha hospital, on October 26. He was a graduate of the Medical College of Maine, in 1887.

Dr. James M. Ferguson, a retired physician of New Orleans, died October 24, aged 77 years. He was a graduate of the New Orleans College of Medicine and was a surgeon in the Confederate Army during the Civil War.

Dr. William Gibson Craig of Springfield, Mass., a graduate of Jefferson Medical College, in 1868, died on November 15, aged 50 years. He was a member of the American College of Surgeons.

Dr. James Henry Honan died at Augusta, Ga., on November 14. He was a graduate of Rush Medical College in 1895, and later studied in Germany under Professor His. He practised medicine for a number of years in Berlin and later in Bad Nauheim. At the time of his death he was professor of diseases of the heart and circulatory system in the University of Georgia.

Dr. James Ward Vance, a graduate of Pulte Medical College, Cincinnati, in 1881, died at his home in Madison, Wis., on October 31, aged 85 years.

Obituary.

FRANCIS LE ROY SATTERLEE, M.D.

NEW YORK.

Dr. Francis LeRoy Satterlee died after a lingering illness at his home in New York City, on November 12, at the age of 71 years. He was born in this city and was a graduate of New York University Medical School in 1868, a member of the New York Academy of Medicine, the New York Pathological Society, the Medical Societies of the County and State of New York, and the American Medical Association. Dr. Satterlee was surgeon to the Police Department for nearly eighteen years, retiring some twenty years ago. He was attending physician at St. Elizabeth's Hospital and consulting physician of the Midnight Mission, and formerly was the attending physician at the Northwestern Dispensary, in the department of skin diseases and rheumatism. For fifty years he held the chair of physics, chemistry, and metallurgy at the New York College of Dentistry. He was the author of a treatise on rheumatism and had written much on gout and allied conditions. A son, Major Henry S. Satterlee, M.R.C., U.S.A., is now stationed at Camp Sherman, Ohio.

RICHARD WEIL, M.D.

NEW YORK.

Dr. Richard Weil of this city, a major in the Medical Reserve Corps and chief of the medical staff of the Base Hospital at Camp Wheeler, Macon, Ga., died of pneumonia on Monday of this week. He was born in this city in 1876 and was graduated from the College of Physicians and Surgeons in 1900. After a post-graduate course in Vienna and Leipsic he returned to New York and was appointed instructor in experimental medicine at the Cornell Medical School, being made full professor a few years later. He was pathologist at the German Hospital, associate visiting physician at the Mt. Sinai Hospital, and assistant director of cancer research at the General Memorial Hospital. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, the New York Pathological Society, the New York Academy of Medicine, the Association of American Physicians, the American Association of Pathologists and Bacteriologists, and of the American Association for Cancer Research. At the outbreak of the war he was commissioned captain in the Reserve Corps and was sent to the training camp at Fort Benjamin Harrison. From there he was transferred to Camp Wheeler and was appointed chief of the medical service with the rank of major.

FRANKLIN PAINE MALL, M.D., LL.D.

BALTIMORE, MD.

Dr. Franklin P. Mall, professor of anatomy at Johns Hopkins University, died November 17. He was born in Iowa in 1862 and was graduated in medicine from the University of Michigan in 1883. He studied later in Leipsic, Heidelberg, and the Johns Hopkins University, where he was appointed an instructor in pathology in 1888. In 1889 he

went to Clark University, at Worcester, Mass., as professor of vertebrate anatomy, remaining until 1892, when he went to the University of Chicago as professor of anatomy, but returned to Baltimore to take the chair of anatomy in Johns Hopkins in 1893. In 1915 he was appointed director of the department of embryology in the Carnegie Institution at Washington. He was a fellow of the College of Physicians of Philadelphia, member of the National Academy of Sciences, associate fellow of the American Academy of Arts and Sciences, and the Society of Experimental Biology and Medicine, and a member of the Commission for Neurological Research of the International Association of Academies, the Wistar Institute of Anatomy, the American Philosophical Society, the American Society of Physiologists, the American Society of Zoologists, and the Society of American Naturalists. He was a trustee of the Marine Biological Laboratory at Woods Hole, Mass., and was president of the Association of American Anatomists from 1905 to 1907. Dr. Mall was the author of "Causes Underlying the Origin of Human Monsters" and "The Fate of the Human Ovum in Tubal Pregnancy"; and was joint editor of the Handbuch der Entwicklungsgeschichte des Menschen, co-editor and one of the founders of the *American Journal of Anatomy* and of the *Anatomical Record*, and was associate editor of the *Journal of Morphology*.

Correspondence.

PROPOSED REGISTRATION OF ALL PATIENTS TAKING OPIUM.

To the Editor of the Medical Record:

Sir:—Your attention and that of your readers is directed to the blanks just issued by the State Department of Health to physicians who have registered with this department in compliance with the requirements of the last narcotic law of this State. This registration is necessary for the privilege of dispensing what are called "habit forming drugs." In this blank will be found a formal demand for the registration of patients by physicians which is not only not called for under the law as passed, but which was actually rejected by the law makers when offered by its proponents, the Department of Health of this city and the so-called Judges' Committee on Narcotic Addiction.

This demand related to information asked by the State Department of Health under the column headed for "disease or habit," together with the explanatory footnote "distinguish between a prescription of a drug given to alleviate pain due to an incurable disease, or one given because of habit." Whether this extra legal procedure on the part of this administrative body is due to ignorance, oversight, or any other cause, it is equally reprehensible, and should be resisted.

The registration with the local health authorities of all persons using opium in the course of an acute illness while under the care of a physician for a period of three weeks, though demanded by the Department of Health, was properly defeated. This was a breach of professional privilege to be resisted at all hazards. The registration of addicts with the State Board of Health was a compromise. It was agreed to by the representatives of all the medical bodies except one. This one I had the honor to represent. We were against every form of registration, which violated professional secrecy, a stand that is now justified by this attempt to exceed the legal requirements of the present law, to what end remains to be discovered.

John P. Davin, M.D.

New York.

IN RE OSTEOPATHY.

To the Editor of The Medical Record:

Sir:—Dr. Douglas Graham's assumption that I am not familiar with what pertains to massage treatment in hospitals is wholly unwarranted. I have great regard for the value of massage in the management of many patients and have utilized it advantageously in a large number of cases.

But there are instances in which massage has not proved curative and where osteopathy has. No one is, or can be, more opposed than I am to all narrowness and exclusiveness in medicine. On the other hand, I wish a fair show to be accorded to all comers who desire it. Now then, I know of more than one osteopath who has benefited those whom neither drugs nor massage have relieved.

Beverley Robinson, M.D.

New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR BREAD AND ITS EFFECT ON HEALTH—ADMIXTURE OF VARIOUS CEREALS—PALATABILITY AND USEFULNESS OF MAIZE.

London, October 23, 1917.

At a meeting of the Medical Society of London, Sir St. Clair Thomson, president, gave an address on the founder and the foundation of the society. Following this was a discussion over war bread and its effects on health, introduced by Drs. R. Hutchison and E. I. Spriggs. The former considered, first of all, the necessity of knowing something of its composition, and so mentioned that the wheat berry consists of three parts—the pericarp, germ, and endosperm. Only about 70 per cent. of the berry is utilized in ordinary white flour, the germ and pericarp being rejected as mere fodder. To economize our wheat it is now compulsory for millers to extract 80 per cent. of the berry as flour, and some of the pericarp and germ is included, making thus the government regulation (G. R.) flour, which is the basis of war bread. Chemically, this is richer than wheat flour in every constituent except starch; particularly is it richer in vitamines and phosphorus. Its absorbability, as compared with white flour, is not settled, but it is not likely to be inferior if the white flour be finely ground. But war bread is not generally made from G. R. flour alone. Other cereals—maize, barley, rice, oats—are allowed. The proportion of these varies, and at present it is found impossible to standardize the flour of the whole country. The cereals added cannot be called injurious, for they are all good foods. Maize has been much criticised, but if properly ground there is no harm in it, and the hostility displayed to it is only due to prejudice. It certainly is eaten with relish in America.

It is not possible to make bread from the present flour, which has the same esthetic qualities as pre-war bread. The darker color is of no consequence, but the lower proportion of gluten, especially when other cereals are added, make the bread less porous. This drawback may be expected to become less when bakers get more experience with the flour. There is nothing chemically injurious in war bread; in fact, it is superior, from a chemical point of view, to white bread. No doubt the quality produced by different bakers and in different localities varies a good deal, but there is no evidence of any serious disturbance of digestion on this account. Patients are apt to blame the war bread for any disturbance of their digestion. When it seems to disagree, the effect of toasting and more thorough chewing should be tried. Dr. Hutchison had not himself seen a patient in whose case it was possible to persuade himself that the bread had affected the digestion injuriously.

Dr. Spriggs said complaints of the use of other cereals than wheat were due to various reasons, such as lack of skill in making it with the new flour. Then few people realized before the war that cereals given to animals were good human foods, and did not know that from oats, barley, or maize we could get many times the food value that was got by turning them first into animal food. Professor T. B. Wood calculated that out of nearly 17 million tons of various kinds of grain used before the war, only 5 millions became human food. This was less than the average production of home-grown corn, which amounted to 6½ million tons. Dr. Spriggs said he had advocated the use in home-made bread of a mixture of barley meal, oatmeal, rice, or maize; one part of meal to two of wheat or war flour. This is a higher proportion than usually employed. Samples of bread made with different proportions and with other cereals were shown; so were breads made with a cereal which had been boiled before mixing with the flour; by this means it was possible to make a spongier loaf.

Professor W. H. Thompson, adviser to the Ministry of Food, noted the importance of getting our protein food from a number of sources, as all proteins are not "adequate" for both growth and maintenance. Even maize had but one-third of its protein of the "adequate" type. He thought much of the trouble was due to ignorance in milling and baking. In early days, millers were not able to grind their maize to a sufficient degree of fineness. Observations are now being carried out which will most likely overcome all difficulties. Dr. E. Kingscote said that in north Italy, before the war, many who lived on maize, having no other food, were healthy and well nourished. The mixture of flours he thought might cause some difficulty; the grinding of the maize was not equal to that of the wheat, and in baking they took different times. Sir St. Clair Thomson remarked that Lettsom mentioned the subject in one of his essays, and gave hints for a substitute for white bread, viz., "Fine flour of Indian corn to be mixed with that of wheat in equal proportions." He also suggested the use of potatoes as a partial substitute for bread, recommending one-fourth of potatoes; and further, he pointed out that the addition of a little ground rice prevented the bread from crumbling.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

RELIEF WORK FOR THE FRENCH WOUNDED—INSPECTION DAY AT AMERICAN ARMY HOSPITAL NO. 1—THE ARMY DENTAL CONTROVERSY.

PARIS, October 23, 1917.

THE cooperation of the American Fund for French Wounded with the American Red Cross is one of the most important steps that has been made in the work of relief for France. The A. F. F. W. is an organization which represents women's work in America. It was established in the early days of the war for the relief of the wounded in France, and during its existence has aided more than 4,000 hospitals. Between 50,000 and 100,000 American women are working continually toward its support. The society is made up of committees all over the United States, there being more than 400. Many of the members who have built up this society felt a keen disappointment in thinking that their work might lose its independence through the coming of the Red Cross in France; but, on the contrary, the American Red Cross Commission in France has filled the workers on this side with enthusiasm, and the results will be a far greater achievement than could have been expected from any individual society alone. There are between fifty and a hundred voluntary workers in France, who are working in the various departments: hospital department, civil, visiting, clerical, etc., and one of the unique features of this organization of women is an automobile service, which is now well known in France, the vehicles of which are operated by women and are a familiar sight throughout the many cities in which they work.

Yesterday was inspection day at the American Red Cross Military Hospital in Neuilly, and it brought to light a number of improvements that are being made almost daily in the organization under military control. Inspection days have only recently been introduced as a part of the weekly routine of the hospital, and they have proved a wonderful inspiration to all the workers, from the scrub-women to the highest in authority. Every Saturday morning the military administrator, Colonel George Peed, accompanied by the surgeon-in-chief, Major James Hutchinson, and others of the medical corps and Mrs. W. K. Vanderbilt, inspect the hospital from cellar to garret. No corner is overlooked. Every room is closely examined, every curtain raised, every drawer opened and the contents inspected down to a pin, and if a particle of dust is to be found or a garment misplaced the head of the department remembers that her goal must be reached before another inspection day, and that goal must be perfection. The military appearance of the hospital has been greatly added to by the fact that the civilian orderlies who are leaving to enlist in other branches of the army, or are being called to other duties, are being replaced by American soldiers. About fifty soldiers are now engaged in ward duty or any kind of work that is necessary. Four American cooks have been put in the kitchen and are rapidly learning the French way of cooking and the dishes that the French "poilus" like best.

The Paris automobile ambulance service, which is an important part of the hospital, has been reorgan-

ized, and is now composed of two sections of forty-five men each, who have recently arrived from Allentown, Pa., where they have been in training with the other sections which are to compose a part of the "United States Army Ambulance Service" for France, and which have arrived in Paris within the last month. The dental part of the hospital, which is said to be the best and most perfectly equipped in the world, has just received a gift of new chairs of the most modern type and an entire set of new dental cabinets with all sorts of new contrivances from the S. S. White Dental Manufacturing Company of America.

And that brings to mind a state of affairs which is the cause of some controversy and deep dissatisfaction. Drs. Hayes and Davenport have been in charge of the dental department of this hospital from the beginning, treating a class of injuries of the maxillaries and mouth, with a success that has elicited the admiration of all who have become acquainted with their work; and these gentlemen are not alone in remarkable accomplishment along these lines. For the first time in history dentistry has become a fixed adjunct to the care and treatment of the army in time of war and the inventive genius of the army operators has created wonders in the treatment of gunshot injuries of this particular class, and dental science has made unprecedented advances in consequence. When the army took over this hospital the men at the head of this department were requested to accept commissions as lieutenants and continue their work under the orders and direction of a medical major in charge of the hospital. This they declined to do and therein lies the germ of a controversy. These dentists, two of the most celebrated in Europe, with private practices comprising royalty and nobility, and aggregating a hundred thousand dollars per year, both well past middle life, naturally consider themselves fully as important and valuable to the service as some of the doctors not yet thirty years of age who have been taken into the medical service of the army with rank of major. Moreover, as their work is of a highly specialized nature and in many respects outside the ordinary treatment by surgeons, they claim to know more about it than a physician, no matter what his rank, and they are unwilling to place themselves under the supervision and orders of a medical man. In sum, they demand that dentistry shall be made an independent department of the army and be under the control of the recognized leaders in their profession of equal rank with their medical brethren, and it is evident that this thought is giving rise to an agitation that will not rest short of congressional or departmental action.

4. Tuberculosis in Cattle.—Curtis M. Hilliard states that tuberculosis in cattle has been more or less neglected by anti-tuberculosis societies because of its relatively low incidence in humans compared with the human type of infection. On the other hand, the fact that the occurrence of bovine tuberculosis in man is absolutely preventable, while the human variety is, at best, reducible only, would seem to make it imperative that the cattle disease should receive prompt and vigorous attention by all agencies and societies that aim at this scourge. The bacillus is found to occur chiefly in the bodies of dairy cattle, but may also infect beef cattle, hogs raised in dairy districts, and rarely other animals, and finally is found in man. Less than 1 per cent. of beef cattle are tuberculous. In dairy herds the disease seems to ravage the Eastern states more than the Western in this country. In New York, from 1910-1912, of 39,330 cattle examined by the tuberculin test, 7171, or 19 per cent. reacted. The Massachusetts commissioner on domestic animals in Connecticut states in the 1916 report "that 30 per cent. of our cattle are infected with this dreaded disease seems probable from those found in the herds, the owners of which have taken advantage of the tuberculin test." The Massachusetts commissioner gives 12 per cent. as an approximate figure for this state. To be extremely conservative, Hilliard states that 10 per cent. of all dairy cattle furnishing milk in our large cities for infants, children, and adults alike, are infected with a disease which is transmissible to man. Milk and milk products are the chief means by which the bacillus is passed from cows to man. The germ rarely infects the milk glands, but when it does a grave menace exists, for there are almost as many tubercle bacilli in the milk as there are in sputum in active human cases, and it will dangerously infect the milk of a large number of cows, when mixed. The disease usually exists as a lung infection in cattle. The nose and throat discharges are infectious and serve as a fruitful source of infection amongst cattle themselves, but special opportunity is afforded for the infection of milk directly from this source. Indirectly, however, the germs from this origin find their way into milk. They are "raised" by coughing, swallowed, and pass through the whole length of the alimentary tract in a virulent condition. In manure they will survive for some time, probably for weeks. Almost all milk contains some cow manure and so it might be anticipated that bovine tubercle bacilli will sometimes be found in milk. Probably between 7 and 8 per cent. of milk in our large cities contains tubercle bacilli. Ice cream, butter, and cheese may also contain tubercle of animal origin. Cream contains several times as many organisms as does the skimmed milk. Examination of these products, especially butter, reveal the presence of the tubercle bacilli far too often for comfort. It might be thought that the salt in butter and its storage in the cold would render the microbes harmless in a short time; while the cold has a tendency to eliminate pathogenic bacteria, Mohler of the United States Bureau of Animal Industry has demonstrated the tubercle bacilli to remain virulent for 160 days in salted butter and for 261 days in cheese. Most investigators will agree that the bacillus will survive for many weeks—time ample for transmission to man. Furthermore the bacillus enters through the mucosa of the intestine most conveniently with a fatty diet, so that these products are of great importance in relation to the problem. Hilliard considers this problem from two standpoints: (1) The elimination of tuberculous cattle. (2) The pasteurization of milk. A careful routine physical examination by the competent veterinary will go a long way to keep a herd free from this disease, of course, employing the tuberculin test. Then in order to procure clean milk, pasteurization must be employed. Hilliard says that we have wrangled for years over the pros and cons of pasteurization, but scientific laboratory investigations and practical results have overthrown these objections. He thoroughly believes in the compulsory pasteurization of all milk, except certified (and the day will come when most of that will be heated also), which comes to our cities.

5. The Danger to Children from Tuberculosis in Cattle.—Richard M. Smith brings out the fact that tuberculosis in children is usually a disease of the bones and glands, and that it enters the body in the vast majority of cases by the digestive tract. He refers particularly to tuberculosis of bovine origin. Tuberculosis from this source represents in general about 25 per cent. of all cases of this disease in children under five years of age. It is estimated that in New York City between 6 and 10 per cent. of the children that die in the hospitals each year of tuberculosis, die of the bovine infection, representing about 300 children a year. Smith considers that there has been but a slow appreciation of the importance of bovine tuberculosis in children, and that we have been very slow to apply the remedy. He states that there are only two ways in which the disease can be eliminated: one is to have milk as it is produced free from tubercle bacilli, and the other to destroy the tubercle bacilli which are present in the milk. Since the process for procuring the first condition is very expensive and will take an immense amount of time, the second method must be applied. This can be done through pasteurization of milk, but it must be properly done else a false standard of security will be established. Strong influence should be exerted to have some sort of inspection or careful and intelligent supervision of pasteurizing plants employed if the method of pasteurization is to be adopted generally.

6. Ventilation and Cubic Space for Infants in Institutions. A Report.—The Public Health Committee of the New York Academy of Medicine has published a report with reference to ventilation in connection with infants in institutions, the same having been prepared by Thomas S. Southworth, William L. Stowell, and Philip Van Ingen, as a joint subcommittee of the Public Health Committee and the Pedicatric Section of the New York Academy of Medicine. The committee recommends that: (1) The present law relating to ventilation in institutions for children, which is utterly inadequate, should be abrogated and superseded by legislation which would be based on definite and scientifically grounded standards. (2) The air space allowed should be from 1000 to 1500 cubic feet for a child, especially for sick babies. Artificially fed babies, owing to the frequency of digestive disturbances, their susceptibility to illness, and their high mortality, should be rated as sick babies. There is no essential difference between institution wards and hospital wards when the infants are artificially fed. The longer stay in the institution than in the hospital increases the susceptibility to illness and malnutrition, and at least equalizes the requirements for space. New-born infants might be allowed less space for the first two weeks of life, if nursed at the breast. (3) When the rooms are very high the cubic space for a child should be made liberal to prevent proximity of beds. Each bed should have 100 square feet of floor space. (4) In order to minimize the danger from cross infection, beds and cribs should be separated from each other by a distance considerably greater than the two feet required by the present law. Six feet would make a desirable distance between beds. (5) All rooms, and particularly those in which artificially fed infants are kept, should be provided with devices for proper window ventilation at all seasons. (6) The State Department of Health should possess the exclusive power of control and regulation, and no local board or department of health should have the power to alter the standards specified in the law. Exceptional permits to deviate from the normal standards may only be granted by the State commissioner of health upon the recommendation of an accredited inspector, accompanied by a written report showing adequate grounds for such recommendation. (7) Frequent inspection should be required, at irregular intervals.

2. Prophylactic Therapy for Rickets in a Negro Community.—Alfred F. Hess and Lester J. Unger, realizing that for many years cod liver oil has been regarded as the sovereign remedy for rickets, decided to investigate whether its usefulness could not be extended to the prophylactic treatment of this disease. Since about 90 per cent. of the colored babies are subject to rickets, these men chose a negro community in New York, known as Columbus Hill, in which to carry out their investigations. This district, having a population of about 9,000, bears the unenviable distinction of having the highest mortality of any neighborhood in the city, being New York's "black spot." They began their work on about eighty infants between the ages of 4 months and a year, belonging to families in which the other children showed evidences of the same disease. Physical examinations were made and records kept with an examination at the end of two, four, and six months. Of course many mothers did not keep up the therapy, so at the end of the six months only forty-nine babies had been given the full treatment. Results showed that the development of rickets was prevented in more than four-fifths of the infants who received the oil for six months, and in more than one-half of those who were given it for four months. Of the sixteen infants who did not receive the oil, fifteen showed signs of rickets, though all of them lived under the same conditions and many in the same families. No other treatment was given, nor was a change of diet or mode of life attempted which could account for the difference in the results in the two groups of cases. The oil proved to be a more potent factor than breast feeding in warding off rickets, as almost all the colored babies developed rickets even when breast fed. They further state that it is difficult to tell either the minimum length of time that the oil must be given to accomplish prophylaxis or the minimum dosage necessary. Results showed, however, that a four months' course of treatment, averaging a total of from 16 to 20 ounces of oil, is insufficient to afford protection. It would seem that a six months' course of treatment should be considered the minimum duration for beneficial results. Their plan was to give infants under 6 months one-half teaspoonful of oil three times a day, and older infants twice this amount. It was found that almost all babies can take cod liver oil, although it may disagree temporarily and may have to be discontinued for short intervals when there is digestive disturbance. Infants of from 2 to 3 months tolerate the oil in half-teaspoonful doses, and younger ones may be given still smaller amounts. This study was not carried out during the summer months, so that it does not provide a criterion of the practicability of oil therapy in the warm weather. As the result of personal experience gathered at other times, these men believe that with slight modification it can be pursued throughout the year. In summer, moreover, rickets seems to pass through a quiescent period; therefore treatment is not so necessary as in the colder season. The results of this investigation by Hess and Unger have been so satisfactory that they have led to the establishment of a rickets clinic in Columbus Hill by the Department of Health, in connection with its baby welfare station, where cod liver oil will be dispensed at cost.

1. Report upon an Investigation into the Effects of Cold upon the Body.—Norman C. Lake conducted these investigations and found that a reinvestigation of "frost bite" was also necessary, for if the effect of "chilling" of the tissues is to produce a state of suspended animation, then it would be illogical to accept theories which assumed a direct effect of a degenerative and destructive nature. The term "frost bite" is here used in its widest sense, and includes such conditions as "trench foot." He offers the results of his investigations as follows: (1) The temperature—60 C. must be considered critical in relationship to the effects of cold upon the tissues. (2) Degrees of cold below this temperature produce true frost bite and actual damage to tissues. (3) Degrees of cold above this temperature only produce effects secondarily by causing vasomotor paralysis. (4) Nerve blocking does not prevent either the effects of frost bite or chilling. (5) The use of vasoconstrictors delays the swelling in cases of true frost bite, while in cases of chilling the exudation may be entirely prevented. (6) Satisfactory treatment of trench foot must be directed towards preventing any appreciable rise in capillary pressure. (7) In the production of trench foot cold must be considered the essential factor, other factors being either secondary or subsidiary. (8) Treatment by the use of vasoconstrictors, either intravenously or otherwise, would appear logical and worthy of trial. (9) Treatment by nerve-blocking, either regional or central, is also suggested, although, in all probability, it cannot be expected to give good results unless used in conjunction with vasoconstrictors. (10) Prophylaxis consists in using any and every means of preventing congestion of the legs, and in avoiding, as far as possible, variations in the temperature. (11) The question as to whether any surgical procedure, such as temporary occlusion of the arteries, would bring about the desired reduction in capillary pressure is being investigated.

4. Reinfection in Syphilis; with Observations on 28 Cases.—Charles F. White states that probably there is no such thing as a natural immunity from syphilis. However this may be, it was held until recently that immunity from syphilis might be acquired. The older theory, now abandoned, was that one infection of syphilis produced immunity from further infection; in other words that syphilis could be acquired but once in a lifetime. Careful investigation appears to have established (1) that reinfection can take place, and (2) that such reinfection cannot take place until the original infection has been completely cured. Since the introduction of the combined salvarsan and mercury treatment for syphilis the number of cases of genuine reinfections reported has increased—a sure sign of the curative efficacy of this treatment and a proof that one attack of syphilis does not produce immunity. Perhaps we should not be far wrong in saying that the only persons immune from syphilis are the syphilitics. Formerly proof of reinfection was based on clinical evidence alone and was open to certain fallacies, namely: (*a*) *In the Case of the First Attack.*—Absence of positive proof of syphilis in those cases in which treatment was started in the primary stage and in which secondary symptoms did not develop. As no microscopic examination was made, or in the failure to find spirochetes in serum from the sore, it was always possible that the diagnosis was mistaken. In other words, there was no positive proof that the chancre was syphilitic and not a soft sore. (*b*) *In the Case of the Second Attack.*—(1) A soft chancre, (2) a recurrent chancre, (3) a chancriform gumma, or (4) a pseudochancre (that is, a mucous genital syphilide which may have undergone induration), being mistaken for primary syphilitic chancres, or (5) the recurrent rashes being perhaps put down as fresh secondary syphilides and regarded as proof of a second attack. Since the discovery by Schaudinn and Hoffmann of the *Spirochæta pallida* as the cause of syphilis and the introduction of the Wassermann serum test as an aid to its diagnosis and cure, positive proof of reinfection can in certain cases be given apart from the clinical evidence. The following conditions may be offered: (1) In the first attack, *Spirochæta pallida* being found from the chancre or syphilitic lesions (condyloma, mucous patch, or rash) or the blood giving a positive Wassermann reaction (here we must exclude the positive Wassermann of cases of hereditary syphilis); and (2) in the second attack, *Spirochæta pallida* being found from the new chancre which appeared at a different site from the first chancre, and the blood at the same time giving a negative Wassermann reaction, which of course implies that the patient must have been seen shortly after the appearance of the second chancre, or at least before the blood had had time to become positive. Twenty-eight cases divided into two series are reported showing reinfection, treatment, and, with disappearance of all signs and negative Wassermanns, considered cured. These twenty-eight cases of reinfection occurred in a series of 10,500 cases of syphilis treated in No. ——— General Hospital during the past two years. One example of these cases is here given. CASE VI. *First Admission* (Sept. 6, 1915).—Signs of infection: (1) Sloughing primary papular syphilitic sore on end of prepuce; (2) glands in both groins hard and enlarged. No other visible sign. Incubation period, five weeks; noticed sore seventeen days after exposure. *S. pallida* present on dark-ground examination. Treatment: Eight injections of 0.3 gram salvarsan and five weekly injections of 1 grain mercury cream. Treatment completed Oct. 12, 1915. *Second Admission* (Mar. 24, 1916).—Signs of infection: (1) Hard sore beneath prepuce—unable to completely retract foreskin; (2) glands in groin slightly enlarged. No other visible sign. Last exposure to infection two months before; noticed sore two weeks before admission. *S. pallida* present on dark-ground examination. Wassermann reaction negative. Treatment same as on first admission; completed May 9, 1916.

Correspondenz-Blatt für Schweizer Aerzte.

September, 1917.

Anatomical Investigations into the Frequency of Tuberculosis.—Reinhart has made autopsies for about 30 months in the Berne University pathological department with especial reference to the frequency of tuberculosis. During this interval he made 460 autopsies. The twenty-eight newly born infants were free from all suspicion of the disease. Of 72 other children (under 16) 21 showed evidences, but of this number only 12 died of tuberculosis. In the other 9 cases, however, the disease was active and progressive, and no child presented any evidence of latent or healed foci. Judging from these figures nearly 30 per cent. of all children are tuberculous. In other clinics the percentage varies from 10 to 42, average of 11 clinics about 27. The author's and other figures show that from 18 to 20 represents the fatal age for tuberculous incidence, for at that period the ratio suddenly doubles. Of 360 sections in adults (from 16 years upward) no less than

347 showed some evidence pointing to tuberculosis (over 96 per cent.). This is more than treble the ratio in childhood. The 13 negative cases occurred in the younger adults by preference. The author's figures are notably higher than those of other clinics with the exception of Zürich (97-98 per cent.). Dresden gives 91 per cent. but other German cities are very much lower or, roughly speaking, a third less. But of these 347 patients only 80 actually died of tubercle, equal to 22.2 per cent. The author includes the smaller calcified lesions under tuberculosis, but even if these are not reckoned the percentage is 87.5. Of 247 cases of tuberculosis in which the disease was not responsible for death only 37 were of the active progressive type, all others showing cicatrization or calcification with a majority of foci in the lungs and bronchial glands. The enormous percentage of autopsy tuberculosis at Zürich and Berne should not beget pessimism but optimism. It teaches that while practically every one is tuberculous the disease takes a relatively small toll of life.

Emetine and Psoriasis.—Jadassohn refers to several favorable reports concerning the action upon psoriasis of emetine. The author's colleagues having called upon him to test this remedy he secured some ampoules of the hydrochloride and began to treat them with certain psoriasis cases of moderate severity. He began with 0.01 and increased very gradually to 0.03, one injection daily, without the development of a toxic reaction. The largest total quantity injected was 0.68. Locally, indifferent ointments were applied. Of 4 cases thus treated not one showed any response; while the deep injections into the buttocks were decidedly painful. It is possible that larger doses over longer intervals would have secured a favorable response, but the author will leave that for others to test.

Correspondenz-Blatt für Schweizer Aerzte.

September 15, 1917.

Dangers of Intrauterine Pessaries.—Guggisberg states that extrauterine pessaries properly adjusted are universally recognized as a gynecological resource. As to the intrauterine varieties the profession are divided in opinion. When used for therapeutic purposes it is rather by the family practitioner than by the specialists; for the latter do not sanction it either in textbooks or in the clinic. But the author is moved to write chiefly against the great danger of using the intrauterine apparatus to prevent conception. Historically considered the therapeutic pessary was freely used by some of the founders of gynecology but not for long as the dangers soon asserted themselves. The ordinary vaginal pessary then came to replace them. The author is considering now the purely supporting pessary. The use of tents and bougies is, of course, another thing, and even gynecologists sometimes make use of them. This is the case especially in infantile uterus with amenorrhea and in mechanical dysmenorrhea. But even this use is risky and repudiated by many specialists. At present Fehling's glass tubes with lateral windows seem the least objectionable, but the requirements for avoiding danger should be very strict. Patients must keep their bed and the duration of treatment should not exceed three weeks, naturally between menstruations. While such tubes permit menstruation to take place no chance of this kind should be taken. In regard to so-called "sterilettes" or obturators to prevent conception, these must be clubbed at the upper extremity to prevent their slipping out; while the lower extremity is provided with an occlusive concave disk which is intended to prevent all entrance of spermatozoids in the uterus. While physicians, unfortunately, sometimes introduce these instruments, it is the charlatan, the masseuse, and midwife who are especially active in this direction. Many women learn the art of introducing them on their own persons. The dangers from their use are manifold. Occasionally a portion of the pessary is left behind as a foreign body, while faulty introduction has caused numerous accidents of perforation of the uterus into the adjacent cavities. But the widest danger is from allowing these instruments to remain *in situ* for further copulation. If used at all, the least thing to do should be withdrawal after coitus. When allowed to remain in, infection of some kind is almost certain to result. Abundant statistical material is available on this score. Thus Gummert collected the following series of accidents following the anti-conceptional use of obturators: deaths, 13; womb colic, 29; irregular intrauterine hemorrhages, 29; purulent endometritis, 57; exudates, 61; pressure ulcers, 5; perforation into anterior fornix, 4; into bladder, 1; into rectum, 2; peritonitis, 37. The slightest injury has led to fatal sepsis. But this is not all. These eminently occlusive structures do not always prevent conception. Gummert found 92 cases in which conception took place despite the use of the sterilette. Further, no less than 78 of these pregnancies ended in abortion, chiefly septic in character. The author gives notes of two cases of extrauterine pregnancy which followed the use of the apparatus and cites another from the practice of Jung. It is, therefore, abundantly evident that this custom is both highly dangerous and uncertain. The condition is serious enough to require legal intervention but difficulties are at once obvious. It has already been stated that there is a limited legitimate use for intrauterine pessaries and a law against manufacture or import would work hardships. Not a few sterile women have been made to conceive through the use of Fehling's tubes. A law making a physician's prescription mandatory for the sale of these instruments would not solve the problem. One point has not been touched on, a very important one, viz., the danger of abortion to a pregnant woman who leaves a sterilette *in situ*. But this, of course, is entering into quite another subject, for there is no limit to methods for accomplishing this end. The only question of interest here is the possibility of regarding the sterilette as under the head of abortifacient material. It is probably used deliberately for such a purpose to a vanishingly small extent because other measures are superior.

Journal de Médecine de Bordeaux.

September, 1917.

Improved Technique in the Research in Stools for Parasitic Ova.—Carles and Barthélemy discuss methods of intensive research, such as are pursued in sputum diagnosis for the discovery of parasitic cysts and ova—especially for the entameba of dysentery—in the stools. One method recently advocated is the following. After having thoroughly homogenized the stool, place about 20 c.c. of it in a 125 c.c. graduate and add formolized saline solution 10 per cent. to make a homogeneous emulsion, which must be strained through a wire or cloth strainer. The fineness of the latter must stand in direct relation to the size of the ova sought. A number 32 will give passage to the ova of worms, as the spaces measure 225 micromillimeters. For the entameba, No. 90 will give it passage, the interstices measuring 60 microns. The filtrate thus obtained is now centrifuged for 1 minute at 1800 revolutions. The supernatant fluid is now suddenly decanted off and the sediment diluted with a solution of citric acid in water containing formol (acid 12, water 86, 40 per cent. formol 2, density 1047). To this mixture 1 or 2 c.c. of ether are added and the whole shaken strongly. The whole is now centrifuged for 30 seconds, 1800 revolutions. Since cysts, etc., may be caught at the zone of separation between the ether and heavier fluid this should be disturbed with a pipette and centrifuged a second time. The ether and supernatant fluid are quickly decanted off and the sediment should now be free of all food residues, large formed elements and much bacterial life, and if any ova or minute cysts are present they should be readily found in smears stained with lugol. The word enrichment as applied to this kind of method means simply concentration with elimination; and since the culture countries have made an intensive study of tropical disease in their colonies the helminthologists have developed numerous technical resources in the research for parasitic ova in the feces. The author, however, criticizes some of the procedures in use; while at the same time speed of procedure is not necessarily a factor with the pure naturalist. The clinician must have a rapid and infallible method which agrees in all respects with rapid tests for Koch's bacillus in the sputum. In the author's procedure the density of the

acid solution used is not a mere detail but represents an optimum for the discovery of protozoan cysts. Citric acid is moreover a great improvement over the chlorhydric acid used by helminthologists; while sulphuric ether is by far the best solvent for all the fatty matters. This acid is too strong to spare delicate tissues and its density (1171) is too high. The selection of straining apparatus is also vital for complete success as is also the speed of the centrifuge. In both these requirements the author has been compelled to discard the technique of helminthologists as unsuited to clinical demands. Naturally the criterion for superiority of method is the character of the field obtained—the relative number of objects per field at low powers.

Chronic Enteric Syndromes and Military Service.—Lauboy and Marre speak of the increasing frequency of chronic bowel troubles among the formations at the front. Some soldiers were predisposed to these affections at the start while others have developed them solely as a result of army life. These troubles are obscure in nature and apparently devoid of causes. One of the more striking forms is a colitis attended with constipation. The patients complain of a good deal of pain and pass formed mucus. It would appear that in these cases constipation is the basic trouble. After a period of obstinate constipation a reaction of diarrhea sets in which may be brief or prolonged. In some patients constipation and diarrhea alternate and the diarrheic periods may last the longest. The stools show that the diarrhea is not a true one but only a false, reactionary one. Mucus may be loose, or ribbon like or may be a complete cast of the bowel. Pain may be continuous or critical and always precedes the reactionary diarrhea. The condition should yield after a course of treatment. In a second type of colitis diarrhea is present throughout. This is more common than the preceding. Although the bowels are loose the number of movements need not be large—in fact there may be only a single daily evacuation early in the morning. Other subjects have, in addition to this stool, one or two others during the day. In the worst cases there may be a number of evacuations. Aside from the difference in the number of stools the condition is always the same as shown by the character of the stools. Other types are a pseudo-dysentery which may be associated with ulcerative and hemorrhagic colitis. Sharply distinguished from the colonic types given above is true chronic diarrhea, which is simply precipitate evacuation of the contents of the small intestine. This affection represents true diarrhea and may be nemogenic or due to local irritation, especially seen in infectious enteritis. In regard to prognosis colitis from constipation and ulcerative colitis are the most obstinate while putrid discharges are also an unfavorable element. With either putrefactive or fermentative diarrhea, there must be inferior utilization of foods as well as constant loss of albumin. The weight and temperature are important in prognosis. There should be a routine use of the symoidoscope and bacterial control of the stools in all rebellious cases. Test meals may be of value.

Reflexes from Percussion of the Sole in Diagnosis.—Rimbaud compares this resource with percussion of the tendo Achilles. There is a difference of opinion among authorities in this regard for while some claim that the two resources give the same result others flatly contradict this statement. The author finds that as a rule one act simply corroborates the finds of the other but also claims that percussion of the sole of the foot may at times give specific reflexes. In the normal subject the foot *per se* is flexed and the toes are separately flexed. But while flexion of the foot is the same for percussion anywhere of the sole, flexion of the toes varies with the area percussed. Flexion of the foot is of precisely the same character as that induced by percussion of the tendo Achillis, i.e., is tendinous in nature. Flexion of the toes, on the contrary, is a muscle reflex which varies with the muscle percussed. Flexion of the foot as a whole is absent in sciatic lesions just as it is in percussion of the tendon, but flexion of the toes is abolished only when there is a complete interruption of innervation in the sciatic or internal popliteal.

What Is Arthritism?—Fernet states that we may regard good health as a diathesis—a "eutrophic diathesis"—which is relatively rare. Starting with this idea we may imagine the existence of any number of dystrophic diatheses, some of which represent slight, others profound departures from good health. In the past we have had arthritic, rheumatismal, herpetic, scrofulous, syphilitic, tuberculous, and other so called diatheses which are only too often confounded with infectious diseases—tuberculosis, syphilis, etc. At the other extreme diathesis has been confounded with temperament—sanguine, bilious, nervous, lymphatic. The author can see only three real diatheses, viz., scrofulous, arthritic, and herpetic. The tuberculous and syphilitic diatheses, so called, are conditions which result from the diseases or infections themselves and which differ throughout from actual diatheses, which are inborn, not acquired conditions. Upon a diathetic foundation diseases develop, some because of the diathesis, others in despite of it; but even the last named are sensibly modified by the constitutional state. We no longer believe in the existence of a rheumatic diathesis, for rheumatism we now know to be due to Achalme's bacillus which causes a general infection. As far as chronic rheumatism is concerned, it is far from being an entity, but certain types doubtless occur in subjects with the arthritic diathesis and at times represent pure gout. Scrofula, so called, is a diathetic entity, which may readily be studied in the child, occurring as it does by preference in the offspring of very poor, often alcoholic parents. These victims are undernourished and deprived of air and light and the condition is manifested as an insufficiency of the lymphatic system which invites or modifies the infections of childhood, of which the chief is tuberculosis. So called herpetism or the herpetic diathesis has been freely discussed but its nature seems quite unknown so that the author does not recognize its independent existence; for him it should be a sort of subdiathesis of arthritism. This narrows the field to two basic conditions which should be antagonistic. Just as scrofula is due to undernourishment so arthritism should depend in some way on overnourishment. Just as one is preeminently a disease of the poor the other affects only the well to do. However, idleness is a factor no less important than dietetic excesses. The other view is that arthritism is not a plus but a minus condition, characterized by slow metabolism. This view the author rejects because an arthritic subject does not exhibit anything sluggish or indolent in his diseases which are the very reverse—hyperacute, painful, suggestive of irritation. Like scrofula, arthritism can be inherited from the wrong kind of parents. Aside from true gout, chiefly a disease of advanced life, we see arthritic manifestations in adolescence and early maturity—skin diseases, asthma, congestions and hemorrhages, headaches, and migraine, hemorrhoids, neuralgias, calculus diseases, etc., etc. The arthritic takes cold very easily and another quite constant early manifestation is dyspepsia. In late life an entire series of the diseases of this period may be brought into relationship with arthritism which, moreover, may apparently be a factor in cancer. The rôle it plays in cardiorenal disease and arteriosclerosis is, of course, notorious. The arthritic complicates his condition with abuse of alcohol, etc., and thus sets up vicious circles. Arthritism is most readily recognized through the polymorbidity of the subject and the apparent migration of disease from one locality to another. No one plan of drugs, or diet, etc., can cure arthritism, but there must be a complete inversion of all the methods of living which have fostered its development.

Formaldehyde in the Treatment of Pyodermatoses.—Aschner has treated with great success cases of various suppurative affections of the skin, including boils, with 4 per cent. formaldehyde solution applied with a brush. —*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

FRACTURES OF THE LOWER EXTREMITY OR BASE OF THE RADIUS. By LEWIS STEPHEN PILCHER, A.M., M.D., LL.D., of Brooklyn, N. Y., Consulting Surgeon, Bushwick, German, Jewish, St. John's and Bethany Deaconess Hospitals, Norwegian Deaconess Home and Hospital, New York Skin and Cancer Hospital; Editor of the Annals of Surgery. Pages 116, with 132 illustrations. Price, $2. Philadelphia and London: J. B. Lippincott Company, 1917.

VERY early in his professional career Pilcher became especially interested in fractures of the lower end of the radius, and this interest has persisted to the present time. In this book the author first goes carefully into the anatomy of the bony and ligamentous structures involved and shows the mechanism of fractures of the lower extremity of the radius. He does not employ the term "Colles's fracture" because he feels that "names descriptive in anatomical or pathological terms of a surgical condition are much to be preferred when it is possible to phrase them" and also that "the use of the name in question has been so associated through all these years with erroneous views of the nature and cause of the injury that its continued use tends to hinder the general acceptance now of more accurate knowledge."

The different varieties of displacement of the lower fragment or fragments, the not infrequent splitting of the lower end of the radius, and the reasons for these conditions are discussed *in extenso* and all these conditions are profusely illustrated by drawings and radiographs. Epiphysial separations, arrest of growth of the radius, the permanent alterations in the contour of the base of the radius that often take place after fractures, the deformities following unreduced or partially reduced fractures—all these subjects are exhaustively considered. The author's method of treatment is then described and fully illustrated.

The author has made many contributions to the literature of fractures, and this book is written as his final word on the subject. The diction is pleasing, the subject matter well presented, the illustrations are almost uniformly excellent, and the book forms a truly valuable addition to the literature of fractures of the lower end of the radius.

SURGICAL THERAPEUTICS AND OPERATIVE TECHNIQUE. In Three Volumes. By E. DOYEN. English Edition Prepared by the Author in Collaboration with H. Spencer-Browne, M.B. Cantab., etc. Elève de l'Institut Pasteur; Physician et Chef de Clinique de l'Institut Doyen. Vol. I. Pp. 746, with 1034 illustrations. Price per set of three volumes $25.00. New York: William Wood and Company, 1917.

WE have here the first volume of a work written by a master in the diagnosis and treatment of surgical conditions. One naturally expects much under such circumstances, and the reader soon finds that his expectations are to be more than realized. American surgeons are especially fortunate, for this is not a translation of the French edition which appeared some years ago but is taken from the material for the second French edition, which has not yet appeared in the original language; hence is thoroughly up-to-date, and this and the succeeding volumes will contain the latest developments in war surgery and surgical treatment in general. The French edition will consist of five volumes, but the three-volume English edition will contain the complete French text.

In a short introductory chapter Doyen gives a brief historical review of the evolution of surgical practice, then proceeds with the discussion of methods of operating and calls attention to the value of rapid and at the same time careful work. Besides being an unusually keen diagnostician and remarkable operator, Doyen was a mechanical genius, devised many instruments, and otherwise contributed greatly to the advancement of operative technique. The reviewer was aware of these facts, yet was amazed upon reading this book to learn the extent to which the surgeon of today is indebted to Doyen for the comparative perfection of portions of his armamentarium, for at least forty pages are required for the description and illustration of instruments and other apparatus devised or radically modified by him. Doyen's story of his early preparation to enter the surgical field, including the protracted study of special subjects under the best masters in the various branches of medicine, surgery, pathology, and bacteriology, his long training in operative surgery on the cadaver and the practice of exercises designed to increase his manual dexterity, is extremely interesting and will long serve as a model for one ambitious to become a really expert diagnostician and operator. Following the introductory chapter, the book is divided into two parts, the first, of about 475 pages, being devoted to the consideration of matters pertaining to general surgical technique; the second, of about 250 pages, to operations on the head.

Part I contains descriptions of the instruments and various mechanical appliances required in private and hospital work, sections on care of the patient before, during, and after operation, general surgical technique, surgery of the blood-vessels and nerves, autoplastic surgery, destruction of pathological tissues by heat, electro-coagulation treatment of malignant growths, and many other subjects. All through this section we find case reports, personal reminiscences, and various other digressions when lend a personal touch to the text and add materially to its value. In some fields (that of blood transfusion, for example) we find Doyen's methods somewhat antiquated as compared with current American practice, but such cases are exceptional. Doyen gave much time to the study of cancer and to methods for the eradication of malignant growths, and his descriptions of his method of electro-coagulation is of great interest.

In Part II the usual operations on the head, including certain special operations on the eye and ear, are described and illustrated. Certain portions of this section are somewhat disappointing. This applies especially to the text relating to intracranial surgery, where the indications for operations requiring opening of the cranial cavity have received but brief consideration. This seems a pity, since suggestions based upon the wealth of Doyen's experience would have been of the greatest value. Despite these criticisms, it is safe to say that this book will be found interesting and instructive by all American surgeons; and if the same standard is maintained in the two forthcoming volumes, Doyen's work will form one of the most valuable treatises on surgical therapeusis and operative technique that has ever appeared.

GOOD HEALTH, HOW TO GET IT, AND HOW TO KEEP IT. By ALVAH H. DOTY, M.D., Author of "The Prevention of Infectious Diseases," "The Mosquito," "A Manual of Instruction in the Principles of Prompt Aid to the Injured," etc. Illustrated. Price, $1.50 net. New York and London: D. Appleton and Company, 1917.

QUOTING from the preface of this book as follows: "It has been the aim of the author to include in this book the essential and salient points in the construction of the body and function of its various parts; also to discuss public health problems, the maintenance of individual physical well-being, the means by which infectious diseases are transmitted and how they may be prevented, the importance of pure air, good water, and nourishing food, as well as other matters connected with the subject of hygiene. The author has endeavored to present these in a clear and simple manner, and in a way that will make the application of the information practicable in everyday life and conduct." That Dr. Doty has accomplished all he endeavored to do will be apparent to the fortunate readers of this latest work from his pen. A sane, well and attractively written book, which puts forth all the best in practical knowledge of the topics presented in so simple a style that it can be used and understood by any reader of normal intelligence, and at the same time it will prove a delight to those teaching hygiene, first aid, and kindred branches, because it has condensed so much vital material in so small a space. The reviewer has been keenly delighted with the ideas of the author in regard to distribution of meals as expressed on pages 116 and 117. In italics has he placed this sentence, "*breakfast should be the best meal of the day.*" Then he gives the reasons for his statement, which, as many of his readers will know, is in direct opposition to the teaching of the past fifteen years where this meal is concerned.

Society Reports.

SEVENTH CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 831.)

Wednesday, October 24—Third Evening Session.

Symposium on Military Surgery and the Specialties: General Surgery.—Major CHARLES H. MAYO, M.R.C., of Rochester, Minn., stated that it was only through medicine that it had been possible to carry on the war for three years. Without thorough medical efficiency the war would have been terminated through disease and infection and we probably should have had brought upon us a very unsatisfactory peace, which would have been far worse than no peace at all. Through medical efficiency this war would be carried on to a final termination which would end the wars of the present age and democracy would be safe in the world. When war was first declared the medical men of our country responded to the call for the aid of humanity. Probably two thousand of them had been helping in England, hundreds had helped in France, in Serbia, in Russia, and in Italy, and some few hundred in Germany, and we had their experience to aid us. We were proud, from a medical standpoint, that Germany recognized us by dropping bombs on the hospitals, because we were returning 80 per cent. of the injured back to the front. It was unfortunate that the medical profession had not quite the rank to accomplish the things they might be able to accomplish, so that they could go from the country, either as medical men or men in the army with a rank which befitted them, so that they could properly associate with the representatives of France, England, and Italy who were doing the same work. The navy had been recognized and now had just as good rank as that of any country in the world, and all the men of the army should have it. Congress had honored our Surgeon General with the highest honor it was possible to give, by bestowing on him the rank of Major General. They had developed through his sanction and help the greatest post-graduate school in medicine in the world, and there were thousands of our medical men in training. Many of the best medical men objected to taking the training because they didn't understand that without it they would not be able to do any of the work. The training of doctors along military lines was essential and every camp represented a better lot of men. The specialists were doing great work in the Surgeon General's office and nothing was coming out of the office of the Surgeon General with his sanction except things that would stand the test of common sense. This was too serious a time to make any change in the specialties or general surgery or anything else. Robert Jones had 5,000 beds, where he had done most wonderful work in orthopedic surgery, and we were going to have a little better work in that line. The records which had come back showed that on over the top fighting about 10 per cent. received head injuries of some sort; in trench warfare possibly 20 per cent. received injuries about the head of all varieties. We had about 10 per cent. of chest injuries, 6 per cent. of abdominal injuries, and 25 per cent. of the total on the average were fractures to be taken care of. There would be plenty of work for every man and the various specialties were grouped under three headings: General surgery, general medicine, and the laboratory. Under them came all sorts of work of reconstruction, which would mean so much. We were building mobile operating pavilions and connected with them were a few large vans that could be moved about rapidly. They were all standardized and well equipped with everything that had been chosen for the army work in the medical line. As to Carrel's work along antiseptic lines, he had developed the principle of some chemical agent that would not injure the tissues and Dakin as the chemist had carried out his ideas. Dakin took the old Labarraque's solution of lime chloride and by removing the free alkali made it safe for use. But that did not mean that this antiseptic or any other was going to work indiscriminately without common sense and without the judgment of the surgeon. There was no great innovation about the care of injured people; there was the modern application of the principles, but they were not so new. They wanted men of mature age and judgment to put at the head of the hospitals to do the work that was being done now in the base hospitals.

Head Surgery.—Major WALTER R. PARKER, M.R.C., U.S.A., Detroit, said that he had been asked to speak in place of Colonel Lyster because the latter had been detained in Washington on duties incident to the war. One of the first problems to be considered after the sudden expansion of the Medical Corps ot the Army was to determine how to give the army the benefit of the services of those trained in a special branch of surgery, and at the same time construct the necessary organization to make them effective from a military standpoint. One of the steps in carrying out this policy was the grouping of those specially qualified into a unit to be known as Division of Surgery of the Head, the specialties forming the group being ophthalmology, otolaryngology, brain surgery, and oral plastic surgery of the face. In the office of the Surgeon General this division was under the direction of Lieut. Colonel Lyster of the Regular corps, and to each subsection was assigned a member of the Medical Reserve Corps. The first duty of the division had been to secure for the Surgeon General the names of a sufficient number of physicians qualified to do the work, who were willing to serve. In some instances, particularly in brain surgery and oral plastic surgery, there were not enough trained men available to meet the demand, so schools had been established where preliminary training was given. Through the activity of this division 589 officers of the M. R. C. were now on duty or ready to serve, and more than twice that number had signified their willingness to serve. Should the war necessitate the training of three millions of men it was estimated that the number of surgeons required by that section would be over three thousand. Another special duty of the division had been to suggest plans and equipment, and to advise on the personnel of a special head hospital with a capacity of 1,000 beds, authorized by the surgeon general to be erected and operated somewhere in France at the proper time. In that hospital would begin the first work of reconstruction. It was the purpose of the Surgeon General to establish schools of instruction for all the surgeons in the cantonment hospitals. To assist in this work teachers of known reputation had been assigned to take charge of the various divisions and textbooks dealing with the military aspect of each department were being prepared. The spirit shown by the men assigned to duty in the national army and national guard cantonment hospitals had been all that could be desired. In a few instances requests for a higher rank had come to the heads of the various divisions, but only in rare instances had service been refused because of the commission offered. The Surgeon General had authorized him to say that it was the policy of his office to give the higher rank to those of large experience who, on entering the service, were qualified to assume full control of the special service to which they had been assigned. To those in the lower grades it could be assured that merit would be recognized and promotion given whenever it was fitting to do so.

Brain Surgery.—Captain CHARLES BAGLEY, JR., M.R.C., Baltimore, thought the physicians, in common with others, had failed to appreciate the full force of duty until their great work was divided into small parts. He classified the wounds of war surgery of the nervous system as follows:

"1. Tangential wounds, in which the missile, usually a rifle bullet, has passed superficially to the bone, leaving its mark externally in the form of a gutter, with or without fracture or intracranial complication.

"2. Penetrating wounds, in which the missile has passed immediately beneath the bone. In these cases the laceration of the dura and brain is, naturally, inevitable. Bone fragments may penetrate more or less deeply.

"3. Direct localized blows by fragments of shell or shrapnel bullets, which have themselves failed to penetrate the skull, but nevertheless have driven fragments of bone deep into the brain.

"4. Penetrating wounds in which a missile has entered and remained lodged with the brain substances.

"5. Cases in which a rifle bullet has passed across the cranial cavity, the wounds of entry and exit being on opposite sides of the head.

"6. Concussion of the spinal cord, in many instances not associated with external signs of injuries.

"7. Compression of the spinal cord when a detached spicule of bone is driven into the spinal cord, these injuries frequently differing only in degree from those produced directly from a projectile.

"8. Direct localized injuries resulting from fragments of shell or shrapnel in which there may be extensive local destruction and often a considerable amount of blood clot.

"9. Wounds or injuries of the peripheral nerves, of varying degrees, again divided into a small group in which the nerve injury is of primary importance, and much larger group in which the injury of neighborhood structure is of far greater significance."

The problems in the care of this varied group were to combat shock and use promptly whatever revisional operative work might be indicated, to combat infection, and to remove foreign bodies as intelligently as possible. The *x*-ray had been of tremendous assistance in localization and also in directing the removal of fragments. The giant magnet had a limited value and was capable of great harm. Hernia cerebri had proved particularly difficult to treat successfully. Bony defects of the skull and "crippled brains" were not of immediate importance, but indicated to a small degree the tremendous problem of reconstruction which would fall to the division of brain surgery after the war. He made an earnest plea that every possible means be used to reduce the occurrence of epilepsy. The present very small corps of neurological surgeons would have to undergo the expansion now so conspicuous in all branches of the service. A plan had been formulated for training the men who were capable and willing to undertake this special work and schools had been established at various places under the direction of skilled neurological surgeons. After receiving intensive fundamental training, they would be capable of special clinical training in Europe. A book on "War Surgery of the Nervous System" had been compiled by Major M. G. Seelig, in which the complex subject-matter had been condensed. For over three months they had been steadily compiling a list of candidates for this special branch, but were still seriously in need of surgeons. The work must be undertaken in an unselfish and self-sacrificing manner, but if properly done the compensation upon completing might be summed up as follows:

"(1) To the individual soldier, the best service. (2) To the medical department of the army, a small part of the great task, well done. (3) To scientific research the advance that will necessarily come if all specimens are carefully preserved and correlated for post-bellum study. (4) To the civilian population all the advantages incident to the wider dissemination of a broader surgical knowledge. (5) To the individual surgeon, active in the work, the satisfaction of having done his part."

Ophthalmic Surgery.—Major JAMES BORDLEY, JR., of Baltimore said that his committee had been authorized on April 26, and since that time, without an intermission of a single day, it had been working in Washington in an advisory capacity on the many ophthalmological problems of the army. A complete catalogue of nearly 9,000 ophthalmologists in the country had been prepared and they had been able to hand to the Surgeon General the names of over 1,400 men who had signified their willingness and were qualified to serve. More than 300 had been commissioned and more than 200 ordered into active duty. They felt convinced that when the American army was in the field the surgeon general's plans for ophthalmic service would be found adequate. They had caused to be made for the first time in the United States the soda glass necessary in the manufacture of glass eyes which heretofore had been manufactured exclusively in Germany, and a member of the committee acting independently had devised a plan for protecting eyes against injury, which they believed would be of far-reaching value. One member of the committee had been called into active service and assigned to the division of physical reconstruction and reeducation to assist Major King, the chief of the division, in preparing plans for the reeducation of the blind and deaf soldiers. A group of twelve of the leading educators of the blind in this country had been asked to study this complex question with him and on their suggestions Major King had arranged for the field service in France and for the establishment of a teaching institution in this country. Everyone who had given thought to the subject of reeducation of the injured soldier knew that it was essential for the army to hold him in the military service until his reeducation was completed. In order to do that the Surgeon General must have supervision over every stage of the process, and the organization that would have the responsibility of the placing of an injured soldier in a trade or profession should likewise be directly under the surgeon general who was charged with the duty of preparing that man physically for the battle of life. The blind soldier must first, if possible, be reconstructed ocularly and if not, then reeducated and placed in such a position that his future happiness would, as far as possible, be assured.

Surgery of the Ear, Nose, and Throat.—Dr. C. W. RICHARDSON of Washington reviewed the appointment of the various committees and stated that the first activity engaged in by the subcommittee on otolaryngology was the listing of all the known specialists in that branch of medicine throughout the United States and the preparing of an index catalogue. They had discovered that 852 men were available for service; of this number 43 had been assigned to national army cantonments, 34 to national guard cantonments, and 149 others had accepted their commissions and were awaiting assignment to duty. The number that had been assigned to go abroad was 32, and there were 852 others who had signified their willingness to accept service, but had not yet taken out their application papers. Other activities of this committee had been the standardization of otolaryngological instruments; aiding the Surgeon General to assign the proper personnel to cantonments and base hospitals; the revision of hearing requirements for entrance to the army; the assembling of tests for malingerers, and the near perfection of an ear protector. A special hospital and dispensary building for the section of surgery of the head had been planned for the national army cantonment and for the base hospitals abroad. All of these activities had received the approval of the surgeon general. A manual of war surgery of otolaryngology was being prepared by Major H. W. Loeb of St. Louis, and several trips had been made by members of the committee to various cities to explain to otolaryngologists the activities of the committee, and awaken interest in the members of this branch of medicine to their opportunities for service. The names of candidates for commissions unknown to the committee as to their professional qualifications were referred to the advisor in the State from which the candidate came and an accurate account of his qualifications was thus obtained. The committee had also been enabled to suggest the names of the men to be assigned to each of the cantonment special hospitals and they were now preparing a roster of the men to be placed in the base hospitals abroad. The reconstruction, reeducation, and rehabilitation of the defective in hearing and speech among the soldiers was receiving due consideration by this committee.

The Aims of the Subsection of Plastic and Oral Surgery.—Major VILRAY P. BLAIR, M.R.C., U.S.A., of St. Louis, said that the distressing wounds of the face and jawbones had attracted particular attention, not only on account of the disfigurement which they caused, but because of the difficulty which was first encountered in dealing with them. That difficulty was the logical outcome of an attitude that regarded dentistry and surgery as two distinct and separate professions. As long as this theory was allowed to dominate practice, a man who had an extensive injury of the face and jawbone had about as much chance for an ideal result as had the man with an open fracture of the limb in the days when the physician and the bonesetter could find no common ground upon which to meet. The surgeon had expended much study upon making himself master of the various means of splinting an injured limb, but proper fixation of a fractured jaw could only be accomplished by the use of dental splints. These he could not always apply himself and he had not always sought the help that the dentist

could so easily lend. Proper fixation in the early stage was one of the most important points in the treatment. The dentist was not trained to care for the wounded tissues beyond fixation of the bones, yet repair of the soft tissues and proper drainage might be equally important. A few had bridged this no man's land between surgery and dentistry, but he believed that the majority were pursuing their separate ways and that a patient with a jaw injury would be treated either by a surgeon or a dentist, neither of whom was master of all the problems, and that either the fixation or the care of the tissues would suffer accordingly. It had been the custom to transport these men back to special centers, where qualified men were stationed, and in the meantime the patients received what might be called general treatment. We had recently been told that the most important step in the preparation for the care of our wounded was to plan to give them the proper operative treatment within the first twelve hours, and that if this was done the primary union might be obtained in 90 per cent., and that gas gangrene, etc., might by this means be eliminated. He felt convinced that this earlier treatment would accomplish even better results than late treatment where reconstruction must overshadow conservation, and that if the plan of treatment could be started in the earlier hours after the injury it would occasion much less distress to the patient and much less effort on the part of the operator. It was the hope to place in every evacuation, base, and recovery hospital men who were familiar with the problems and technique of dealing with these face and jaw injuries, so that from the very first these patients would receive the very best that surgery had to offer. There were many men in this country who had specialized in oral surgery, many of them with medical degrees, who had gone beyond the treatment of the teeth to devote their attention to the peridental structures. These men understood most of the oral problems, but as a rule were not accustomed to doing the major surgery that was required for many war injuries. It was by associating the capable general surgeon with the dental oral surgeon and sending them out as units that the skill could be furnished in multiple. In orders to correlate the work and to present the special war problems short course schools had been established by the surgeon general in several cities where those surgeons and the dental oral surgeons working together would be molded into working units. Until their services were needed abroad those units were cooperating with the dental surgeons at the cantonments in an attempt to eradicate peridental infections from the mouths of our soldiers. It was hoped by this means to lessen materially the medical casualties on the other side.

Orthopedic Surgery.—Major E. G. Brackett, M.R.C., U.S.A., of Boston thought the problems of the orthopedic surgeon did not differ materially from those of the other departments of medicine except in extent. There were two principal considerations involved in the plan to bring the men who had been disabled back into normal civil life:

I. *The Surgical.*—The quick restoration was the essential element. To avoid the many disabilities which might occur by delayed treatment preparations were made in order that the special care might begin as far back in the line as possible, with the shortest line of communications and with the fewest changes before arriving at that base where the permanent part of the treatment would be given. To insure the early and continuous cooperative care of the men who were to be given special treatment the medical forces, working both in France and the United States were to be guided by the same general plan. For the care of men overseas a number of beds sufficient to meet the demand had been planned and were under way. The hospitals would be built to contain 250 beds each and fitted with the curative workshops. About 70 surgeons were working in the orthopedic hospitals in England under Col. Sir Robert Jones, and many of them would be detailed to take up the work among American soldiers in France when the need arose. Special provision to supply artificial limbs in sufficient numbers was necessary. In order to supply a sufficiently large number of men who would be capable of responding to this work, special training was being given to those members of the M.R.C. who had applied for work in this division.

II. *The establishing of industrial occupational facilities in intimate relation,* both administratively and geographically with the hospital. Thus the curative workshops would be built as part of the hospital equipment so that the men, while still confined to the hospitals might, at the same time, be carrying on their vocational and curative work, and no time would be lost. The work of the orthopedic rehabilitation must be looked upon as having three distinct phases, yet so closely allied and interwoven that they made one problem: (1) The physical restoration. (2) The industrial reeducation to fit the new physical conditions into the existing social relations, which must be resumed. (3) The reinstallation in normal employment. This work of rehabilitation in its three phases was an activity which was most stimulating, for it was not directed alone toward the provision of a temporary emergency, which would end with this military crisis. The need of this same rehabilitative work as a factor in solving our civil and industrial problem had been evident for some time, and already attempts had been made to meet the need through the establishment of such work. Thus the military problem would merge directly into the permanent civil one, and could then be turned over to meet the municipal demands. It would make it one of the lasting contributions which could come out of the disasters of this war.

Thursday, October 25—Fourth Evening Session.

Presidential Address.—Dr. John G. Clark of Philadelphia delivered this address, the text of which was "The Use of Radium in Gynecology." He reported the results in the use of radium in one hundred cases of small myoma uteri and in cases of so-called myopathic hemorrhage, which were usually resistant to curettage and consequently required a hysterectomy to relieve the menorrhagia. In concluding his clinical review of this series of cases, which had been followed up very carefully, Dr. Clark spoke as follows "Radium is the treatment of choice in all cases of small, uncomplicated myomata, whose only symptom is hemorrhage. In these, as well as in cases of myopathic hemorrhage, almost 100 per cent. cure may be expected. Sufficient dosage will produce complete and permanent amenorrhea. In young women, radium should be used with the greatest caution, since its application may be followed by a premature menopause. If other measures have failed, radium may be employed, but in small dosage. Irregular bleeding due to pelvic inflammatory disease, tumors of large size or tumors of any size complicated by diseases of the adnexa or surrounding structures, as well as single myomata in young women, are to be treated by appropriate operation and not by the application of radium. In no case of uterine bleeding should radium be used without a preliminary curettage and microscopic examination of the curettings by a competent pathologist. In properly selected cases the immediate convalescence is smooth and restoration to health is complete. Pelvic pain rarely occurs and as a rule is of but a few days' duration. In the exceptional case leucorrhea follows the application of radium, but this is not permanent. Not infrequently radium has cured or diminished discharge which was present before its application."

As a preliminary statement in his discussion on cancer of the uterus, Dr. Clark stated that they had discovered that the disproportion between operable and inoperable cancer of the cervix was about 1 to 5 in that during ten years 60 cases were found within the operative limits of a radical hysterectomy, whereas approximately 300 were turned away from the hospital as hopeless. The use of radium was confined strictly to the latter class, 100 cases having been subjected to this treatment. Dr. Clark adhered to the principle that operation was the method of choice in the operable cases, for notwithstanding there was a minimum salvage in even a well-selected series of cases this treatment was the best that had been obtained. He therefore adhered to the dictum that when a case was within surgical bounds it should be treated by radical surgical measures. Relative to the inoperable cases, he said: "The remarkable palliative results in cases of inoperable cancer of the cervix have modified our viewpoint as to the cases which fall within the elective surgical class, for our former rule was when in doubt as to the extent

of the growth, operate, but now we reverse the policy, and in doubtful cases we employ radium. Under this restrictive policy, our percentage of operative cases has shrunken, but we trust that the results from a radical hysterectomy will yield better curative results. We justify this conservative attitude by the assertion that in 100 inoperable cases treated by radium local healing has occurred in 52 per cent. This does not mean, however, that all of these 52 patients are alive, for several are dead of metastasis but without return of the local cervical process primarily destroyed by the radium. Even though the patient died from the secondary invasion, this is a remarkable showing as to palliative results, exceeding in our experience all other remedies, and we trust that several will survive the five-year test. One of the terrifying symptoms for the patient and her family is hemorrhages. Of our 100 cases 60 were completely relieved of this symptom. There was a recurrence of hemorrhage in 10 cases and in only 14 it was uninfluenced. Vaginal discharge, other than hemorrhage, was checked in 51; uninfluenced in 15. Of those suffering pain 23 were relieved, and 14 were not relieved. In some cases, the relief of pain was only temporary, varying from a few days to a month or more."

A few surgeons have advocated the use of radium preliminary to a hysterectomy. From this view Dr. Clark was a radical dissenter, for it hardly appeared conceivable that a remedy which worked effectively for at least 2 cm. from its point of application could be improved upon by a surgeon's knife, limited by such insuperable anatomical barriers as the bladder in front, the rectum posteriorly, and the ureters and pelvic vessels laterally. He therefore adhered strictly to one rule, namely, never to attempt an operation on any case that had been healed locally by radium. It appeared to him a most unwise surgical policy to subject a patient to the hazards of a radical operation, rendered more dangerous by the dense cicatricial tissue which formed in the wake of a successful radium application, in what he believed to be a fatuous attempt to secure still more effective results. Indeed, he was inclined to the view that cancerous nests of degenerating cancer cells might actually be liberated and thus render abortive an otherwise good palliative result.

Radium, as was shown in Dr. Clark's series of cases, was by no means an infallible panacea for cancer. There was no way of determining which cases would be benefited by its use. There was beyond doubt a certain percentage, as estimated by his observation, in which cancerous growths were not retarded by radiotherapy; indeed, in an occasional case it would appear that there was a positive acceleration of the growth. That many cases showed an astounding improvement with local disappearance of the ulceration could not be gainsaid. In his series, several instances occurred in which the results achieved were so remarkable as to be almost incredible. In some of these cases the fire was but smouldering and would break out sooner or later with renewed violence, as several of his cases had proved, but upon the whole this treatment yielded, to say the least, highly encouraging palliative results, and he trusted that permanent results would follow in a definite percentage of otherwise hopeless cases.

In the discussion of cancer cases the question of hospital economics must not be lost sight of. The length of stay in the hospital following a radical operation averaged at least three weeks; whereas after the application of radium not more than three days would be required. When complications arose after radical operations they were usually serious, entailing much suffering. Such patients, on returning home, were likely to remain semi-invalids for several weeks or months, and when, as was frequently the case, there was a rapid continuation of the disease, they became a heavy burden to a poor family. In the comparison of statistics, this difference between the two classes of patients was greatly in favor of those treated by radium, a fact that tended to incline Dr. Clark strongly to the use of radium in borderline cases, which formerly he subjected to a radical operation.

Removal of the uterus in cases of cancer of the fundus had yielded such good results that the speaker did not feel justified in taking any chances with radium, even in the borderline cases, except in cases where there was a serious surgical contraindication. In his series of 100 cases, only four were thus treated. He said: "*Our surgical attitude toward the cervical and fundal growths is diametrically opposite. In borderline cases of cancer of the cervix we invariably employ radium. In advanced cases of cancer of the fundus we invariably perform a hysterectomy.*" A pessimistic view dominated the outlook in the surgical treatment of the cervical growths if the pathological process was at all advanced, whereas fundal growths might be viewed with a cheerful optimism even when the cancerous process was extensive. As a palliative agent, Dr. Clark asserted with full assurance that he had never obtained results with any other method that had even approached in beneficence those secured by radium. The treatment was simple and entailed no distress to the patient, and the results in checking hemorrhage were immediate and in a very large number of cases the hemorrhage never returned, even in the fatal cases. Because of the wellnigh miraculous action of radium in the occasional case, there was danger of unbridled optimism and no one should let the occasional astounding result cloud his vision when it came to a judicious consideration of a large series of cases.

In this brief summary Dr. Clark said he had attempted to give a fair and unbiased statement of the benefits, limitations, and dangers of radiotherapy in gynecology. He stated, however, that "our conclusion of today may be completely changed by our experience of tomorrow for the entire field of work is still in the period of probation, but we are certain that the benefits of this remedy are so great that no well ordered clinic can do the best work without it. In our experience, 100 milligrams have been sufficient to serve a most satisfactory purpose in gynecological practice."

War Surgery of the Spinal Cord.—Dr. CHARLES H. FRAZIER stated that under the enlightened scientific administration of the Surgeon-General's office neurological surgery was recognized as needing special training and special facilities, that to that end courses were being established to train surgeons for this work, and special hospitals were planned in the war zone where such cases could be cared for by neurologist and surgeon in cooperation. The spinal cord might suffer in a variety of ways, both directly and indirectly. It might be severely lacerated or even completely severed by direct contact with the bullet or indriven piece of bone, by the bullet protruding into the canal, by a subdural hemorrhage, by adhesions, or serous exudates; it might be contused by the bullet and accompanying splinters of bone, and finally the cord might undergo grave structural changes from the effects of concussion or commotion caused by a bullet striking some portion of the vertebral column and bounding back to become lodged in the soft parts, or the sudden atmospheric changes produced by the explosion of shells in the neighborhood might result in changes in the spinal cord. Considerable interest had been aroused as to spinal concussion. Unlike concussion of brain, structural changes, even to complete disintegration, were a not inconstant feature. In most cases of spinal concussion the bullet struck the vertebral column and rebounded, to become embedded in soft tissue or an organ often at some distance from the spine. The momentum of the modern bullet was so great at the time of impact that the vibrating force was transmitted to the cord with damaging effect. Spinal concussions were diffuse and irregular, and included edema, hematomyelia, hematorrhachis, disseminated foci of necrosis, softening and cavity formation, and parenchymatous changes, often over four or five segments in either direction. Another group existed in which, without either direct or indirect injury to the spinal column, the patient showed grave involvement of the spinal cord and all signs of a complete or partial transverse lesion. These were attributed to atmospheric pressure caused by shell explosion. Dr. Frazier maintained that accurate localization was absolutely essential to successful treatment. Hitherto sensory disturbances of the upper level had been considered the most important guide, but motor disturbances such as paralysis of groups of muscles of the trunk would be found of great value in determining the level of injury. For example, if the eleventh segment was involved, we would find paralysis of the lower portion of the external and internal oblique with bulging of the iliac regions, while the whole rectus abdominalis contracted when the pa-

tient raised his head or coughed. If the ninth segment was affected, the lower part of the rectus abdominalis was paralyzed, while the upper part contracted vigorously. The condition of the intercostals was also a very valuable aid in the localization of lesions, particularly of the upper thoracic segments. By placing the finger over an intercostal space, the muscle would be felt to contract strongly on each inspiration if it was not paralyzed. This was a valuable guide, since each intercostal muscle received its nerve supply from the corresponding thoracic root. In considering level symptoms of lesions between the second cervical and second thoracic mention was made of the results of disturbance of the cervical sympathetic, including the miosis or inequality of the pupils, the narrowing of the palpebral fissure, the enophthalmos, the diminution of tear secretion, flushing of the face, and diminution of sweat. An interesting syndrome in lesions of the lower part of the cervical enlargement was represented by slow pulse, subnormal temperature, low blood pressure, and scanty secretion of urine. The temperature in some cases was lower than could be registered by a clinical thermometer, the pulse rate from thirty to fifty, rising or falling with the rise and fall of temperature, and the urinary secretions sometimes entirely suppressed. This peculiar state of stupor and lethargy had been likened to the condition of the animal in hibernation, both in the symptom complex and in the way in which both reacted to the influence of external temperature. Dr. Frazier described a case recently under his observation with an acute inflammatory condition of the fifth and sixth thoracic segments in which polyuria had been a striking symptom, the patient, a boy of sixteen years, voiding for several weeks from 150 to 200 ounces of urine per day. In all probability the polyuria was due to arrest of function of the vasoconstrictor fibers of the kidney. The *x*-ray had proved disappointing for localization. Dr. Frazier recently examined two *x*-ray plates of gunshot injuries of the spine from the war zone; in the first plate one of the vertebral bodies appeared shattered to pieces but there had been no injury to the cord; while in the other the plate showed no evidence of fracture or foreign body but the case presented all the symptoms of a complete transverse lesion. Fracture of the spinous processes or depressed fractures of the laminæ were not easily brought out by the *x*-ray, and even with stereoscopic pictures it was not always easy to determine whether a bullet lay within or without the spinal canal. However, *x*-ray pictures should be taken routinely in the hope of eliciting the site of a bullet or the presence of a dislodged fragment and to determine if possible whether the bullet was within the spinal canal. The important problem to decide was whether an exploratory laminectomy was indicated and when it should be performed. In indirect injuries, even when the vertebral column was not involved, the symptoms might temporarily simulate a complete transverse lesion. In these cases early operation was contraindicated but if symptoms persisted it might be performed under favorable circumstances on the ground that they might be due to hemorrhage or undetected skeletal injury, and it must be remembered that clinical evidence of complete transverse lesion did not necessarily signify irreparable injury to the cord. Dr. Frazier stated that when dealing with direct injuries to the cord by bullet, shrapnel, or bone splinters the propriety of a laminectomy admitted of little discussion. An exploratory laminectomy should be performed, whether the picture was one of a complete or incomplete lesion, for there was nothing to lose and perhaps something to be gained. In twenty operations for gunshot injuries of the spine Guleke found the cord completely crushed in ten, and while only five of the twenty cases recovered, three of these would have died had not fragments of bone or bullets been removed. Such operations should not be performed until the patient reached a hospital from which he need not be moved, as absolute rest was essential during convalescence. Included among the later indications for operation were the symptoms attributable to the pressure of an organized exudate, of callus, of a traumatic pachymeningitis, or of a circumscribed serous meningitis, and in not a few instances the principal indication for operation was persistent and intractable pain. Dr. Frazier then described the technique and indications for opening the dura.

Dr. Allen B. Kanavel of Chicago, in discussing this paper, presented a lantern slide demonstration of twelve patients operated upon for traumatic injuries of the spine. Ten of these dealt with fractures of the spinal column causing pressure symptoms on the spinal cord. The results to be obtained even in cases operated upon some months after receipt of the injury varied with the site of the fracture. Injuries of the cauda equina presented the best prognosis. In several of these cases the bladder function had been restored, sensation greatly improved and motor power much improved, so that the patients were able to walk with a cane whereas they had previously been bedridden. He emphasized that the greatest care must be used not to injure the spinal cord. That whereas brain tissue might be handled with some impunity, the slightest injury to the spinal cord during the operation was followed by serious results. Two gunshot cases were shown, one in which the bullet had been imbedded in the cauda equina for four years. This was dissected out with care and the patient ceased to complain of the serious pains that he had had and his motor power improved markedly. The second case was one in which the bullet was lodged within the spinal canal at the junction of the base of the skull with the atlas. The patient complained of inability to flex and extend the head without great pain. An incision was made through the mouth and the posterior wall just to the inside of the posterior pillar, since the bullet lay on the anterior portion of the spinal canal. The bullet was removed and the patient made a satisfactory recovery.

Surgery of the Stomach.—Major William J. Mayo, M.R.C., U. S. A., of Rochester, Minn., stated that 30 per cent. of all cancers of civilized man were in the stomach, and that this condition was uncommon in primitive man and in the lower animals, although there was no mechanical and secretory difference in the construction of the stomach. He believed that chronic gastric ulcer was not often cured medically, and was not seldom a source of cancer. He called attention to heat as a source of irritation, and was of the opinion that cancer occurred more frequently in man than in woman because man was in the habit of taking his food and beverages hotter than the average woman did. Woman sat at the foot of the table and poured the tea and coffee, served the men of the household first and drank hers after it had cooled somewhat. In the Chinese the same rule held true with the rice that was eaten, for the woman ate at the second table and the food was cool. It was his opinion that food and drink should not be taken into the stomach hotter than could be borne comfortably in the mouth. The mouth and throat were protected by sensitive nerves, but the stomach was not. Early diagnosis of cancer depended upon the Roentgen examination. The antecolonic end to side anastomosis between the stomach and jejunum greatly accelerated closure. The results of operations for cancer of the stomach were now fairly good and were improving. He reported that 38.4 per cent. were cured.

Dr. A. J. Ochsner of Chicago said we were impressed at once with the fact that a condition to which everyone was exposed was an important condition in the production of this most fatal of all diseases. We had known for a long time that there was no superficial cancer anywhere which occurred without preliminary irritation, and that this irritation gave rise to disturbed circulation. He was of the opinion that human beings were afflicted with cancer because they were manure eaters. We fertilized our soil and in that way took unclean food into the stomach, which produced an irritation. Cancer occurred most frequently at the point at which there was interference with the circulation, and he was convinced that this was a large factor in its production; and that smoker's cancer occurred most often on the lower lip because the circulation was interfered with owing to the weight of the pipe. Although we had not yet found the organism that caused it, we had found the condition that made it possible for this agent to live successfully under those conditions. He thought we should endeavor to avoid all irritation, "stop boiling our insides," and at the same time insist on having clean food to put inside the alimental canal. He was sure that when that was done there would be an enormous decrease in the amount of cancer.

Dr. L. L. McArthur of Chicago agreed with Dr.

Mayo that irritation was a predisposing cause of cancer, and was convinced that irritation made a doorway through which the infective element finally gained access. This atrium he had called attention to in various ways. He was sufficiently neutral to call Dr. Mayo's attention to the fact that the male stomach in Germany had the same frequency of infection as the female, and yet in Germany the man sat at the foot of the table and poured the tea and had his cool. Cancer of the skin had been shown to be due to the yeast plant and had been sloughed off from the great group known as cancer proper. He thought the great lesson to be learned from Dr. Mayo's paper was that the operation formerly considered as formidable was being lessened, and that the extent of the operation continually increased. When hearing Dr. Mayo's remarkable statistics that 38.4 per cent were cured in the understanding of the term that for three years they had lived and were free from evidence of other disease, we were not to decide the fact that this represented the mortality of the stomach when operated upon, but only as the mortality which followed selected cases—not cases selected to improve the statistics to be presented to a medical society, but selected cases in which operation could be performed with reasonable hope of success. The diagnosis was very difficult in many cases even after the abdomen was opened, and when the diagnosis was made even then the prognosis could not be accurately prognosticated. He called attention to an operation for putting the stomach at rest after operation, especially in cases of cancer of the stomach complicated with gallstones, by inserting a tube into the gallbladder and bringing it outside the abdomen. In this way the bile was prevented from getting into the bladder, salt solution could be introduced into the duodenum, the intestines could be flooded, and the patient could be made much more comfortable. Lantern slides demonstrating this method were exhibited.

War Surgery of the Lungs and Pleura.—Colonel Sir Berkeley Moynihan of Leeds, England, read an exceedingly interesting paper on this subject, recounting the experiences of himself and others, from which he drew the following conclusions: (1) The approximate mortality from gunshot wounds of the chest at all parts of the line of communication is 20 per cent. (2) The causes of death are hemorrhage as a rule within twenty-eight hours; and sepsis after the third or fourth day. (3) The local conditions in wounds of the chest wall and lung are in all respects similar to those met with in wounds elsewhere. The missiles are the same, their destructive effects upon the tissues are the same, and the infecting organisms are the same. (4) The lung tissue is more resistant to attack than many other tissues. The opening of the pleural cavity and the resulting exposure of a large serous sac to infection and all its consequences add, however, a danger of the most threatening character. (5) The chief essential in all cases of penetrating wounds is rest. (6) In clean perforating wounds of the chest, rest, together with the cleansing and dressing of the wound of entrance or exist, will lead to the recovery of the great majority of cases. (7) In cases of 'open thorax' the earliest and most complete effort possible must be made to secure closure of the wound after an appropriate toilet. (8) In those rare cases of grave hemorrhage, where hemoptysis is present or when the blood escapes by the wound, a direct access to the source of the bleeding must be obtained, when all contingent circumstances permit, and the wound in the lung must be treated by suture, preferably; or by plugging of the cavity from which the blood escapes. (9) In cases of hemothorax when the blood effused is small in quantity and remains sterile, no active measures are necessary, unless absorption is long delayed. Aspiration, repeated if necessary, may then be performed. (10) In cases of hemothorax, when the blood effused is large in amount and remains sterile, aspiration after the seventh or eighth day, or earlier in cases of urgent dyspnea, certainly hastens convalescence, permits a more rapid expansion of the lung, and prevents the formation of firm adhesions which may permanently cripple the free movements of the lung. (11) In cases of hemothorax, whether the amount of blood is small or large, when infection takes place open operation is necessary. Early operation both when the Carrel-Dakin technique or Morison method are adopted saves many weeks of tedius convalescence and permits of a more perfect functional recovery. (12) Small foreign bodies, or rifle bullets, imbedded in the lung, often cause no symptoms; they become encapsulated and may safely be left. (13) Large foreign bodies retained in the lung may cause distressing or disabling symptoms for long periods. In such cases removal after resection or elevation of the fourth rib through an anterior incision will allow of the safe removal of the projectile from any part of the lung. Pieces of metal so removed are almost always infected.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Louisiana State Board of Medical Examiners.

New Orleans, June 7, 8, and 9, 1917.

(*Concluded from page 838.*)

THEORY AND PRACTICE OF MEDICINE.

1. Name the types of leucemia, and describe the blood pictures of each.
2. A patient presents a continuous type of fever as a cardinal symptom. What laboratory tests are necessary for a differential diagnosis? Describe in detail one of the tests mentioned.
3. (*a*) What symptoms and physical signs are present in gastric ulcer; (*b*) duodenal ulcer; (*c*) gastric carcinoma?
4. Treat a case of acute dilatation of the heart.
5. Differentiate hysteroid and epileptic convulsions.
6. Name five reflexes, and describe the manner of eliciting them.
7. State the symptoms, diagnosis, and treatment of amebic dysentery.
8. Differentiate acute morphinism, acute alcoholism, and apoplexy.
9. Outline briefly the dietetic management of a case of chronic nephritis.
10. (*a*) Describe locomotor ataxia; (*b*) state briefly the symptoms and physical signs in the initial and ataxic stages.

GYNECOLOGY.

1. Give distinguishing symptoms between a four months' pregnancy, a uterine fibroid, and an ovarian cyst.
2. Give the symptomatology and treatment of acute cystitis.
3. What are the methods of replacing the retroverted or retroflexed uterus when movable?
4. What is acute parametritis? Give treatment.
5. Describe the varieties of uterine fibroid, and give characteristics of each which differentiate it from the others.
6. Give a description of the physiology of menstruation.
7. Mention the changes of cervix uteri which may be felt on vaginal examination.
8. A patient presenting herself for examination with a mass in right lower abdomen—what might it be?
9. Give special symptoms pointing to tubal pregnancy.
10. What symptoms may follow retroversion of the uterus?

SURGERY.

1. Describe ligation of the external carotid.
2. What are the symptoms of post nasal adenoids, and their treatment?
3. How would you diagnose glaucoma?
4. Name a few complications liable to occur in a male suffering with gonorrhea.
5. What are hypothyroidism and hyperthyroidism; name the characteristic symptoms of each condition.
6. Give symptoms of fracture of the skull base.
7. What is a Pott's fracture? How would you treat it?
8. What is a carbuncle. How would you treat one?
9. Give diagnosis and treatment of acute osteomyelitis.
10. Make a differential diagnosis between coma due

to (*a*) apoplexy, (*b*) opium poisoning, (*c*) acute alcoholism.

MATERIA MEDICA.

1. Give action of chloral.
2. Give the physiologic action of a toxic dose of atropine, and mention its antidote.
3. What is amyl nitrite and what are its uses?
4. Name three emetics and give dose of each.
5. Write a prescription for a diuretic mixture.
6. What is emetine? Give dose and its action.
7. What is eserin? Give the average dose.
8. What is the action of urotropin?
9. Give the dose of Dover's powder, pulv. jalapæ co., elaterin, apomorphine, and strychnine.
10. What remedies would you give in a case of carbolic acid poisoning?

OBSTETRICS.

1. Name and describe the signs of pregnancy as determined by touch.
2. (*a*) What is the "second stage of labor"; (*b*) what conditions may cause delay in this stage; (*c*) how should such conditions be managed?
3. A primipara at the fourth month of pregnancy presents evidences of albuminuria, with no uremic manifestations; what treatment is indicated?
4. (*a*) What drugs are of use in labor; (*b*) state their indications and contraindications.
5. (*a*) State the maternal and fetal indications for the use of forceps; (*b*) what are the prerequisites necessary for their safe application.
6. What are the planes and axes of the pelvis, and mention briefly their obstetric importance?
7. A transverse presentation has been diagnosed, left scapula anterior; the membranes have been ruptured; how is delivery best affected?
8. What degree of pelvic contraction would be prohibitive of delivery by Nature's efforts at term?
9. (*a*) State the causes of precipitate labor; (*b*) dangers; (*c*) management.
10. Describe the application of forceps in the inferior strait.

ANSWERS.

THEORY AND PRACTICE OF MEDICINE.

1. There are two types of *leucemia*—(1) the *lymphatic*, and (2) the *splenomedullary* or *myelogenous*. In *lymphatic leucemia* there is an enormous increase in the number of white cells, chiefly in the lymphocytes, which may be 90 per cent. of the whole number; the polynuclears are diminished; there are no myelocytes; the red cells are not much affected, but may show a slight diminution in number and in hemoglobin content. In the *splenomedullary* variety the white cells are enormously increased (sometimes equaling or even exceeding the red cells in number); the polynuclears are relatively diminished, myelocytes are present in great numbers; the red cells are generally diminished, and the hemoglobin reduced; normoblasts and gigantoblasts are present.

2. Continued fevers are found in typhoid, pneumonia, tuberculosis, typhus, erysipelas, scarlet fever, smallpox. Laboratory diagnosis includes the Widal reaction and the diazo reaction for typhoid, and an examination of the sputum in the case of tuberculosis.

To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic, is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

3. In *gastric ulcer* "the degree of digestive disturbance varies. The tongue is clean, there are generally nausea and vomiting. There is tenderness over the epigastrium, with pain in the same region from a half to two hours after food, also often referred to the back, and relieved by vomiting. Hematemesis may cause anemia with a hemic murmur and weakness. In the acute ulcer hemorrhage is copious, in the chronic ulcer small occasional hemorrhages are the rule. In a certain number of cases melena is present. Constipation is frequent; there is no fever.

"*Ulcer of the duodenum.* The signs and symptoms much resemble those of gastric ulcer, with the particular features that the pain is nearer the right costal margin and its time incidence is later—two, three or four hours after food. The pain is relieved by taking food which causes closure of the pylorus and so prevents the onward passage of acid chyme over the ulcerated surface. Vomiting is not so common and does not relieve the pain. Hematemesis is rare, but melena is common."

In *gastric carcinoma* "a tumor may be felt, most often in the region of the pylorus, next in the epigastrium over the transverse colon, or there may be merely rigidity of one rectus muscle (more often the right). Secondary nodules may be found near the navel, in the liver, lungs, and lymphatic glands: a group of the latter just above the left clavicle is frequently palpable. According to the situation other conditions may arise—a dilated stomach if the growth is at the pylorus, a contracted stomach if at the cardiac end, adhesions, fistula or peritonitis, ascites—from implication of the peritoneum—edema of the legs from secondary deposits in the retroperitoneal glands pressing upon the inferior vena cava. Pain between the shoulder blades, or in the lumbar region. It is more constant than in chronic gastritis or ulcer, and has no relation to food or the period of ingestion. Vomiting may be absent; if present it will not relieve the pain, and may also have no relation to food. Anorexia is almost always present. Hematemesis occurs in about 50 per cent. of cases only, the blood is only rarely like that in gastric ulcer, but is usually much altered—the so-called *coffee-grounds vomit*. Cachexia (a condition of the body resulting from wasting with anemia) is much more marked than in any other pathological condition of the stomach. A leucocyte count is of value, for post-prandial leucocytosis is absent. Constipation is often present."—(Woodwark's *Manual of Medicine.*)

4. "*Dilatation of the heart is incurable.* The symptoms may, however, be temporarily relieved and the course prolonged. In all cases the indications are to improve and maintain the general nutrition of the patient and to control and steady the cardiac action. The first indication is met by a generous diet, moderate exercise, and the administration of stomachics, red wine, iron, etc. The second indication is met by strict observance of the rules of hygiene, by moderate exercise, and by the administration of heart tonics, such as digitalis. The combination of tincture of strophanthus with digitalis is very beneficial. Strychnine sulphate, gr. 1/24, three times daily, citrated caffeine, gr. i to iii, three times daily, and sparteine sulphate, gr. ⅛ to i, three times daily, are also valuable heart tonics and stimulants. Morphine sulphate, in small doses hypodermically, often acts like magic in restoring the circulation, especially when compensation is failing, and dropsy and cyanosis become marked. The bowels, skin, and kidneys should be kept in action, using, if needed, purgatives, diaphoretics and diuretics. The treatment of cardiac dilatation and cardiac failure by baths and systematic exercise is sometimes advocated. Exercise is employed in one of three methods: (1) passive exercise and massage (according to the so-called Swedish or Ling plan); (2) movements with limited resistance (according to the Schott plan, which is really little more than a modification of the Swedish plan); (3) method of climbing or walking up graduated ascents (after the method of Oertel). The baths are those of the Nauheim (saline) natural waters.—(From Hughes' *Practice of Medicine.*)

5,

EPILEPSY.	HYSTERIA.
1. No apparent cause.	1. Cause, emotional.
2. Sudden and rapid onset.	2. Onset gradual, usually after some mental excitement.
3. Aura generally present.	3. Globus hystericus or palpitation.
4. Consciousness lost.	4. Consciousness generally preserved.
5. Pupils generally dilated.	5. Pupils normal.
6. Tongue often bitten.	6. Tongue never bitten.
7. Patient very liable to hurt himself.	7. Patient not liable to hurt himself; may injure others.
8. May be involuntary bladder and bowel discharges.	8. Never.
9. Of short duration.	9. Duration longer.

6. FIVE REFLEXES. *Plantar:* Elicited by stroking or scratching the sole of the foot, when the patient attempts to withdraw the foot. *Tendo Achillis reflex:* when the leg is extended and supported at the knee, and the hand is pressed firmly against the ball of the foot, a tap on the tendo Achillis causes contraction of the gastrocnemius and soleus, and the heel is jerked up. *Patellar reflex:* when the thigh is supported by being crossed over the other thigh, and the leg is flexed at the knee, a tap on the quadriceps tendon just below the patella causes the leg to be suddenly extended. *Ankle clonus:* if the half-extended leg be supported at the knee, and the ball of the foot be suddenly pressed up, putting the tendo Achillis on the stretch, there sometimes results a series of contractions of the muscles of the calf with alternate extension and flexion of the foot, which continues so long as pressure is maintained on the ball of the foot and ceases when the pressure is released. *Cremasteric:* when the inner surface of the thigh is irritated, the testicle on the same side is retracted.

7. AMEBIC DYSENTERY. *Symptoms:* It is usually ushered in by an attack of diarrhea, accompanied by slight fever, nausea, and vomiting. There are intense abdominal pain and a constant desire to go to stool. The stools become more frequent and bloody. Tenesmus is worse in the afternoon and at night. Temperature may be normal or slightly elevated (100° F.). Intermissions occur in the disease, and the *Amœba coli* is found in the stools. The *diagnosis* is made by finding the microorganisms in the stools, in conjunction with the symptoms. The *treatment* consists of rest in bed and liquid diet. Laudanum (30 drops), followed in half hour by ipecac, gr. 30, repeated, if necessary, has been recommended for internal administration. Rectal irrigations of plain water, silver nitrate solution (gr. 20-30 to the quart), creolin (4 drams to the quart), or quinine (1:5000 to 1:1000) constitute the best treatment. Pain is relieved by opium. Emetine hydrochloride, given subcutaneously or intravenously, is also recommended.

6. The following table is from Eisendrath's *Surgical Diagnosis:*

APOPLECTIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; sudden onset. If any injury, only a scalp wound.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse full and slow, often arteriosclerotic, high-tension pulse.	Pulse more rapid than normal, and full.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Regular respiration.	Respiration very slow — may be 6 to 8 per minute.
Temperature higher on paralyzed side, but lower in rectum.	May be low or normal.	
Urine contains trace of albumin, but may be same as in uremia.	Normal.	Normal.
Hemiplegia with convulsions on one side.		

9. *In chronic parenchymatous nephritis* the *diet* is important. "An exclusive milk diet is impracticable, even harmful. The cereals, with fruits and the lighter vegetables are all permissible. Meats in small quantity are allowable, either light or dark. The water intake must not be regulated by any hard-and-fast rule, but it should be proportioned to the freedom of diuresis. If there is marked edema, especially if it be on the increase, attempted flushing of the kidney is provocative of harm. Under these circumstances water is among the most difficult substances for the kidney to excrete. If the edema is slight or subsiding rapidly larger quantities of fluid are not only permissible but advisable. The intake of salt should be limited to the minimum, as it is pretty generally conceded that its presence in the diet aids the development of edema." (Williamson's *Practice of Medicine.*)

10. *Locomotor ataxia* is a disease of the spinal cord, characterized by loss of coordination, characteristic and unsteady gait, a tendency to stagger when standing up with the feet together and the eyes closed, sharp and paroxysmal pains called *crises*, girdle sensation, Argyll-Robertson pupils, and loss of knee-jerk and other reflexes. In locomotor ataxia the posterior columns of the spinal cord and the posterior nerve roots are involved. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion. The spinal ganglia may also be affected and the membranes over the affected parts are adherent and opaque.

In the *pre-ataxic stage*, there may be found: Lightning pains, girdle pains, paresthesia, loss of knee-jerk, Argyll-Robertson pupil, ptosis, and optic atrophy. In the *ataxic stage*, there will be found: Incoordination, the ataxic gait, flaccidity of the muscles, loss of muscle sense, various visceral crises, perforating ulcer of foot, brittleness of bones, and Charcot's disease.

GYNECOLOGY.

1. *Pregnancy at four months:* The tumor is hard and does not fluctuate, and is situated in the median line; the cervix is soft, and some of the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ovarian cyst: Absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

2. ACUTE CYSTITIS. *Symptoms.*—Frequent urination with tenesmus and a burning sensation in the urethra later on pain in the bladder; the urine may be alkaline and turbid, and may contain blood, mucus, bacteria pus, and epithelial cells. Chills, rapid pulse, fever, and headache may also be present.

Treatment includes: Rest in bed; administration of plenty of cold water or milk, diuretics, bland and mild

foods, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.

3. *Methods of replacing a retroverted or retroflexed uterus when movable* are: The bimanual method, with the patient in the dorsal position; replacement with the patient in the knee-chest position; (the uterus may then be kept in position by means of a pessary). Ventral suspension, and shortening of the round ligaments are the usual operative methods.

4. *Acute parametritis* is a pelvic cellulitis, consisting of inflammation of the connective tissue between the folds of the broad ligament. *Treatment:* "In the acute stages the patient is confined to bed, the bowels kept regular by means of saline purgatives, and warm vaginal douches should be frequently administered by a careful nurse. Glycerin tampons help to relieve the pelvic congestion. When there is much abdominal pain, warm fomentations to the hypogastrium give great relief. When suppuration occurs and the pus can be localized, an incision should be made into it and the abscess drained. It is preferable to evacuate a pelvic abscess through the belly-wall rather than by an incision into the vagina. Should the abscess burst into the vagina, the aperture of communication is apt to close, and defective drainage leads to re-accumulation of pus; under these circumstances, it is advisable to dilate the opening to insure drainage. When the abscess is due to suppuration of a gestation sac the sinus should be enlarged, and all fragments of bone and other fetal tissues removed. The patient's strength must be supported by nutritious and easily digestible food; quinine and iron preparations are useful, and health is finally restored by change of air."—(Sutton and Giles' *Diseases of Women.*)

5. *Varieties of uterine fibroid:* Fibroids may be situated entirely within the muscular wall of the uterus, when they are known as *interstitial* or *intramural;* they may bulge inwardly into the uterine cavity, when they are known as *submucous;* or they may bulge outwardly beneath the peritoneum, when they are known as *subserous* or *subperitoneal.*

6. *Physiology of menstruation:* "The endometrium, in the four or five days preceding the flow, becomes rapidly thicker and its superficial layers are congested with blood and, in places, small collections of blood may be noticed. Opinions differ very much as to the change undergone by this thickened membrane during the flow. According to some authors, most of the membrane is thrown off and the blood escapes from the denuded surface mixed with pieces of the membrane. According to others, no material destruction of the membrane occurs, the blood that escapes being due to small capillary extravasations or perhaps mainly to a process of diapedesis. It would seem that the amount of destruction of the endometrium must be subject to individual variations. After the cessation of the flow the mucous membrane is rapidly repaired by regenerative changes in the tissues; the surface epithelium, if denuded, is replaced by proliferation of the cells lining the uterine glands and the thickened, edematous condition of the membrane rapidly subsides during a period of six or seven days. The mucous membrane of the uterus may be said to exhibit a constantly recurring menstrual cycle which falls into four periods: (1) Period of growth in the few (five) days preceding menstruation, characterized by a rapid increase in the stroma, blood vessels, epithelium, etc., of the membrane. (2) The menstruation or period of degeneration (four days) during which the capillary hemorrhage takes place and the epithelium suffers degenerative changes and is cast off more or less. (3) The period of regeneration (seven days) during which the mucous membrane returns to normal size. (4) The period of rest (twelve days) during which the endometrium remains in a quiescent condition."—(Howell's *Text-book of Physiology.*)

7. By vaginal examination we can determine the following changes of the cervix uteri: Variations in its position, shape, size, or consistency; lacerations, erosions, ulcerations, discharges, and tumors.

8. A *mass in the right lower abdomen* may be: Appendicitis, fecal impaction, intussusception, floating kidney, pyosalpinx, ovarian tumor or abscess or cyst, hematoma or hematocele, inguinal hernia, fibroid tumor.

9. *Symptoms of tubal pregnancy* are the signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, slight enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

10. The *following symptoms may follow retroversion of the uterus:* Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms,* as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

SURGERY

1. *Ligation of external carotid artery:* "An incision is made about three inches in length, along the anterior border of the sternomastoid, or slightly in front of this border, from the level of the middle of the thyroid cartilage to near the angle of the jaw. Incise skin, superficial fascia, and platysma. Tie any veins which may lie in the line of incision. Divide the deep fascia and expose the anterior border of the sternomastoid and draw it outward. Find the posterior belly of the digastric at the upper angle of the wound. Next, locate the hypoglossal nerve crossing the external carotid below the origin of the occipital artery. Locate the tip of the great cornu of the hyoid bone, opposite which the lingual artery arises. Having fixed the location of these three structures, and avoiding the superior thyroid, facial, and lingual veins; expose the artery opposite the tip of the great cornu of the hyoid. Clear the sheath and pass the ligature between the superior thyroid and lingual branches—guarding the descendens hypoglossi nerve in front, and the superior laryngeal nerve passing behind the artery—directing the needle from the internal carotid."—(Bickham's *Operative Surgery.*)

2. *Symptoms of adenoids:* Mouth-breathing; snoring; open mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters. The nasopharynx is more or less filled up by a mass of lymphoid tissue, which can be felt by the examining finger and seen by posterior rhinoscopy. The patient is very susceptible to nasal catarrh, deafness, and obstruction of the Eustachian tube. *Treatment* consists in thorough removal of the growths by a curette, under a general anesthetic. The child must be taught to breathe through his nose.

3. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness.

4. The *chief complications of gonorrhea in the male* may be: Cystitis, epididymitis, prostatitis, vesiculitis, periurethritis, bubo, retention of urine, stricture, gonorrheal rheumatism, and arthritis.

5. *Hypothyroidism* is the name given to the symptom complex found when the thyroid gland is absent, degenerated, atrophied, or is functionally deficient. There is arrested growth, dry and swollen skin, pale and puffy face, swollen abdomen, hair thin and with a tendency to fall out, weak muscles, the nervous system seems undeveloped, mental dullness, lowered body temperature, diminished sexual activity, lower sensibility, and accumulation of adipose tissue.

Hyperthyroidism is due to an increase of thyroid secretion; there will be noticed lowered blood pressure, rapid pulse, excessive perspiration, nervous excitability, digestive disturbances, loss of fat, and in extreme cases exophthalmus, dilatation of pupils, sleeplessness, and tremors.

6. FRACTURE OF BASE OF THE SKULL. The *Signs* are those of (1) injury to the brain, (2) escape of cranial contents, (3) injury of cranial nerves. (1) *Injury to*

the brain may be of the nature of concussion, compression, or laceration. (2) *Escape of cranial contents*, which may be blood, cerebrospinal fluid, or rarely brain itself. (1) *Hemorrhage* manifests itself in various situations, according to the position of the fracture. In the *anterior fossa* the bleeding may be from the nose or into the orbit, or may pass back into the pharynx, be swallowed, and subsequently vomited. The eye may be pushed forward and pulsate if the cavernous sinus be ruptured. In the *middle fossa* blood usually runs from the ears; but slight bleeding from the ear may be caused by minor injuries, such as rupture of the membrana tympani, tearing of the lining of the auditory canal, and fracture of the tympanic bone. In the *posterior fossa* a hematoma may form behind the mastoid process. (2) The escape of *cerebrospinal fluids* is a certain sign that a fracture communicates with the subdural space. It may appear in the same situations as hemorrhage, but is usually found escaping from the ear owing to fracture of the petrous bone. The fluid is limpid, specific gravity 1005, with no albumin, but containing pyrocatechin, which gives the same reaction as sugar with Fehling's solution. The amount which escapes may be small or very large, but as a rule it soon ceases. (3) *Injuries to the cranial nerves* vary according to the site of fracture. That most commonly involved is the facial, in the aqueductus Fallopii, and the paralysis may come on immediately from rupture, or after two or three weeks from the pressure of callus. —(From *Aids to Surgery.*)

7. *Pott's fracture* is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus; then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about three inches above the tip of the malleolus. At the same time the foot is displaced outward or outward and backward. In many cases, however, the displacement is slight.

Treatment: "An anesthetic should always be given, and the fracture reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on the back-splint, with side-splints in addition. The foot must he at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of Paris. Other splints used are Dupuytren's and Syme's horseshoe splint. Massage and passive movement at the end of ten days are advisable, the fragments being firmly grasped to prevent displacement."—(*Aids to Surgery.*)

8. *Carbuncle* is a localized inflammation of the subcutaneous tissue, which has gone on to sloughing. Staphylococci are the exciting cause; diabetes, albuminuria, infective fevers, and lowered vitality are the predisposing causes.

The disease begins as an infiltration of a patch of subcutaneous tissue, which is hard, painful, and tender, and the skin over it red and hot. The infiltration may extend till it is the size of a dinner-plate, and the inflammation ends in sloughing and suppuration, not only of the subcutaneous tissues, but of small areas of the skin over it, so that openings develop in the skin, and allow of the exit of pus and sloughs. The openings extend, the sloughs separate, and the wound heals by granulation. The back is a common situation. Sometimes the face is affected, and there is then a danger of thrombosis extending to the cavernous sinus and producing pyemia.

Treatment: Anesthetize, scrape away the slough, treat the surface with pure phenol, dress with antiseptic gauze, and give the patient good food and tonics.

9. *Osteomyelitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone. It is characterized by: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present

It is to be *diagnosed* from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is *in* the joint, and not *near* it. (2) *Tuberculous arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis*, in which the bone and periosteum are not affected, and in which there is always a wound.

In *osteomyelitis*, the *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

10. The following table is from Eisendrath's *Surgical Diagnosis:*

APOPLECTIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; sudden onset. If any injury, only a scalp wound.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse full and slow, ofter arterioscleotic high - tension pulse.	Pulse more rapid than normal, and full.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher on paralyzed side, but lower in rectum.	May be low or normal.	
Urine contains trace of albumin, but may be same as in uremia.	Normal.	Normal.
Hemiplegia with convulsions on one side.		

MATERIA MEDICA.

1. *Action of chloral:* It is a hypnotic and antiseptic; it is a depressant of both the cardiac and respiratory systems; it lowers the blood pressure and the body temperature.

2. *Symptoms of poisoning by atropine:* "In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterward highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration."

Treatment: Lavage of the stomach; morphine may be given cautiously during the period of violent excitement. Maintain respiration; strong coffee by the mouth or rectum is beneficial. Pilocarpine may be given, in not too large doses, to stimulate the secretion of saliva."—(From Witthaus's *Essentials of Chemistry.*)

3. *Amyl nitrite* is a clear, yellowish liquid, containing about 80 per cent. of amyl nitrite $C_5H_{11}NO_2$; it has a peculiar fruity odor, and an aromatic and pungent taste. It is *used* to relieve high arterial tension, and to dilate the blood vessels; it is chiefly employed in cases of angina pectoris and cardiac dyspnea.

4. *Three emetics:* Apomorphine hydrochloride, dose 1/12 grain (to be given hypodermically); copper sulphate, dose 4 grains; zinc sulphate, dose 15 grains.

5. *Prescription for a diuretic mixture:*

℞.

Potassii acetatis.
Potassii bicarbonatis.
Potassii citratis āā ʒjss.
Aquæ q.s. ad ʒvj. M.

Sig.—One tablespoonful t.i.d.

6. *Emetine* is an alkaloid found in ipecac. It is used as an expectorant, emetic, and diaphoretic. The dose of emetine hydrochloride is 1/3 grain.

7. *Eserine* is an alkaloid obtained from physostigma. The dose of eserine salicylate is 1/60 grain.

8. *Urotropin,* when taken, is decomposed in the body, and formaldehyde is liberated and eliminated in the urine; hence it is used as a urinary (and intestinal) antiseptic.

9. *Dover's powder,* dose 8 grains; *pulv. jalapæ co.,* dose 30 grains; *elaterin,* dose 1/20 grain; *apomorphine,* dose of the hydrochloride 1/20 grain as an expectorant, 1/6 grain as an emetic (by mouth), and 1/12 grain as an emetic (hypodermic); *strychnine,* dose 1/40 grain.

10. In case of *carbolic acid poisoning,* sodium sulphate or magnesium sulphate should be given in water; alcohol is also of service; warm mucilaginous drinks, warmth to the body, emetics, and cardiac and respiratory stimulants are all indicated.

OBSTETRICS.

1. *Signs of pregnancy as determined by touch:*

(*a*) *Ballottement* is the passive movement of the fetus *in utero,* obtained by tapping the lower segment of the uterus with the index finger.

(*b*) *Hegar's sign* consists in a thinning and softening of a segment of the body of the uterus immediately above its cervix.

(*c*) *Braxton Hicks' sign* consists of intermittent contractions of the uterus at about the fourth month of pregnancy.

(*d*) *Rasch's sign* is fluctuation felt when the hand is applied to the cervix of the uterus in early pregnancy, due to the presence of liquor amnii.

(*e*) Active movements of the fetus, which can be felt by the physician's hand placed over the abdomen of the mother.

2. The *second stage of labor* is that part of labor which begins with the complete dilatation of the os uteri and ends with the birth of the child.

DELAYED LABOR. *Causes:* Obstruction, uterine inertia, uterine exhaustion.

Management: The case should be treated early; causes should be removed when possible; a warm vaginal douche, and the administration of morphine, chloral, or quinine have been recommended; delivery by forceps may be necessary.

3. *Albuminuria with no uremic manifestations:* "The urine should be examined every month in the first six months of every pregnancy, no matter how normal it may seem, and every fortnight in the last three months. If albumin is present, the amount should be estimated in an Esbach tube, and the urea in a Doremus ureometer. The total quantity of urine per diem should also be ascertained. The principles of treatment are to relieve the kidneys by free elimination by the bowels and skin, and by diminishing the nitrogenous part of the dietary; and at the same time to prevent any further interference with the renal functions by guarding against cold. In mild cases where the albuminuria is the sole symptom, the patient should be warned to rest and guard against cold. The diet should be restricted to milk food, with bread and butter, and a little fish or chicken once a day, and the bowels should be made to act freely once every day.—(Johnstone's *Textbook of Midwifery.*)

4. DRUGS USED IN LABOR. Bichloride of mercury, lysol, phenol, creolin, etc., are *indicated* as antiseptics for the vulva, and hands of physician and nurse. Boric acid and silver nitrate are *indicated* for use in the infant's eyes, to prevent ophthalmia. Quinine and strychnine are *indicated* in primary and secondary uterine inertia, but are contraindicated in eclampsia. Morphine is *indicated* early in labor in case of weak and inefficient pains and rigid os; if given later there is danger of fetal asphyxia. Chloral is *indicated* as quinine, strychnine and morphine. Veratrum viride is *indicated* in eclampsia and vascular hypertension; it is *contraindicated* in cases with slow and soft pulse. Chloroform and ether are *indicated* in the latter part of the second stage of labor to alleviate the suffering, and also in all obstetrical operations; chloroform is *contraindicated* in cases of very rapid fetal heart, and where the mother has cardiac disease; ether is *contraindicated* in cases of bronchiectasis, tuberculosis and eclampsia. Ergot is *indicated* in postpartum hemorrhage; it is given during the third stage to ensure good contractions of the uterus; it should *not be given* before the third stage of labor. Pituitrin is given for postpartum hemorrhage, secondary inertia, and induction of premature labor; it is *contraindicated* if the os is undilated, and must be used cautiously if the soft parts are not prepared for immediate delivery.

5. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions lkely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both (Jewett).

Conditions necessary for the use of forceps are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

6. The *planes of the pelvis* are imaginary levels taken at any place through the pelvic cavity. The most important of these are the plane of the inlet and the plane of the outlet. A knowledge of the size or diameters of these planes is of value in understanding the mechanism of labor. The *axes of the pelvis* are imaginary lines drawn through the centers of these various planes, and at right angles to their surface. The axes of a great number of these planes would form a sort of circular curve, which represents the course of the fetus through the pelvis during labor.

7. *In a transverse presentation, when the membranes have been ruptured,* "the treatment will vary according to the degree of dilatation of the cervix, the condition of the patient, as well as that of the fetus and uterus. If the cervix is only partially dilated, while the child is alive and freely movable in the uterus, bipolar version may be attempted. After a foot has been brought down the cervix should be allowed to dilate still further before extraction is completed. On the other hand, if the condition is complicated by prolapse of the pulsating cord, the cervix should be dilated manually, and the child rapidly extracted after internal podalic version. Whenever the cervix is fully dilated, internal podalic version should be performed at once, and followed by immediate extraction, provided the uterus is not so tightly contracted down over the child and the lower uterine segment so thinned out that such a procedure appears synonymous with rupture. Even in such cases anesthesia sometimes so relaxes the organ that version may be safely effected, although at first glance it had appeared to be out of the question."—(Williams' *Obstetrics.*)

8. In contracted pelves, with a true conjugate of 7 centimeters or less spontaneous delivery is not to be expected.

9. PRECIPITATE LABOR. *Causes:* Unusually large pelvis, small fetus, excessive force and frequency of the pains, excessive laxity or deficient resistance of the pelvic outlet. *Dangers:* Lacerations, premature detachment of placenta, rupture of the umbilical cord, postpartum hemorrhage, shock, asphyxiation of the fetus. *Treatment:* In cases where precipitate labor is considered a possibility, the patient should be kept indoors for the last week of pregnancy, and should previously have been forbidden violent exercise. She should be put to bed on the first indication of a labor pain, and she should be instructed not to bear down with the

pains; an anesthetic should be administered to diminish the violence of the pains. The nurse should exert pressure (with a sterile towel) against the pelvic floor.

10. *Manner of using forceps:* "They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking, one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis."—(*Pocket Cyclopedia.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	J. W. Thomas, Phoenix	Phoenix	
Arkansas	T. J. Stout, Brinkley	Little Rock	
California	C. B. Pinkham, Sacramento	Sacrameoto	Jan. 8
Colorado	David A. Strickler, Empire Building, Denver	Denver	Jan. 1
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 12
Delaware	J. H. Wilson, Dover	Dover	Dec.
Dist. of Col'ba.	E. P. Copeland, Washington	Washington	Jan. 8
Florida*	W. M. Rowlett. Tampa	Jacksonville	Dec. 4
Georgia	C. T. Nolan, Marietta	Atlanta / Augusta	May 30
Idaho*	Charles A. Dettman, Burke	Pocatello	April 2
Illinois	F. C. Dodds, Springfield	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 8
Iowa	G. H. Sumner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Feb. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. Leckert, New Orleans	New Orleans	Dec. 6
Maine	F. W. Scarle, Portland	Portland	Mar. 12
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 11
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston	Mar. 21
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 11
Minnesota	T. McDavitt, St. Paul	Minneapolis	Jan. 2
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	St. Louis	Dec. 17
Montana*	S. A. Cooney, Helena	Helena	
Nebraska	J. J. Hompes, Lincoln	Lincoln	
Nevada	S. L. Lee, Carson City	Carson City	May 6
N. Hampshire	Walter T. Crosby, Manchester	Concord	Dec. 10
New Jersey	A. MacAlister, Trenton	Trenton	June 18
New Mexico	R. K. McClanahan, East Las Vegas	Santa Fe	
New York	H. H. Horner, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo	Jan. 29
N. Carolina	H. A. Royster, Raleigh	Raleigh	June
N. Dakota	G. M. Williamson, Grand Forks	Grand Forks	Jan. 1
Ohio	, Columbus	Columbus	Dec. 4
Oklahoma	R. V. Smith, Tulsa	Oklahoma City	Jan. 8
Oregon	B. E. Miller, Portland	Portland	Jan. 7
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia	Jan.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

Therapeutic Hints.

A Substitute Dressing.—Sterilized newspapers are being used in the dressing of clean wounds and have given great satisfaction, causing no irritation or disturbance whatsoever. Newspaper, however, was not found to be sufficiently absorbent for suppurating wounds. It can be used as padding under plaster, and paper bandages can readily replace the ordinary bandages, as they are pliable and strong. Paper such as is used in the making of towels, tablecloths, toilet paper, etc., can be applied to clean wounds with good results.—*Journal of the American Medical Association.*

Psoriasis.—In the treatment of this condition, Sutton advises as a preliminary measure the removal of superfluous scales by means of soft soap and warm water rendered alkaline by the addition of carbonate of soda or borax and applied with a stiff brush. This is to be followed by the application night and morning of the ointment of official ammoniated mercury alone, or with the addition of from 2 to 5 per cent. of salicylic acid. This may be alternated with an ointment compounded according to the following prescription:

℞ Tinct. picis carbonis compositæ (Duhring) ..... ʒj (4.0)
Amyli pulveris ..... ʒv (20.0)
Zinci oxidi ..... ʒv (20.0)
Calaminæ ..... ʒv (20.0)
Glycerini ..... ʒiiss (10.0)
Aquæ ..... q.s. ad. ʒ vj (180)

Ointments are best applied with a stiff brush such as an old toothbrush.

Arthritis Deformans.—Scott advises regulation of the diet and hygiene with constant watchfulness as to improvement of general health. Before serious structural changes have occurred, cod-liver oil should be massaged into the affected joints and this should be combined with the internal administration of effervescing lithium citrate in doses of one drachm three times daily, together with the following tonic:

℞ Mass. ferri carbonat. ..... gr. v (0.30)
Liquor. potass. arsenit. ..... ♏ v (0.3)
Vini xerici ..... f ʒ j. (4.0)
Aquæ destill. ..... f ʒ j. (4.0)

M. Sig.—After meals, well diluted.

Also the internal administration of guaiacol carbonate, gr. v to x (0.3 to 0.6 gm.) three times daily, together with painting of the joints, when painful, with the following:

℞ Guaiacol ..... 1 part.
Tinct. iodi ..... 6 parts.

M. Sig.—Paint over joints twice daily.—*Hughes' Practice of Medicine.*

Acne.—Stelwagon employs the following for internal administration in this troublesome condition:

℞ Sodii benzoat ..... ʒss to ij. 2 to 8 gm.
Tinct. nucis vomicæ ..... f ʒij 8 cc.
Fluidextract. cascaræ ..... f ʒij to iv. 8 to 16 c.c.
Tinct. cardamom. comp. ..... q.s. ad. f ʒiij 90 c.c.

M. et Sig.—Teaspoonful dissolved in water three times a day after meals.—*Hughes' Practice of Medicine.*

PROBING THE MIND

NORMAL AND ABNORMAL.

FIRST REPORT.

FEELING, ASSOCIATION, AND THE PSYCHOREFLEX.

BY J. VICTOR HABERMAN, A.B., M.D., S.M.D., (Berlin).
NEW YORK.
INSTRUCTOR IN PSYCHOTHERAPY AND CLINICAL PSYCHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ATTENDING PHYSICIAN, DEPARTMENT OF NEUROLOGY, VANDERBILT CLINIC, N. Y.

BY mind we mean the psychical phenomena consequent upon cortical activity, the interaffection and modification of this, and the retraceable record of it stored in the brain. The study of these phenomena, when normal, we term psychology.

At first thought, it would appear as if the examination of abnormal mind would entail the same usual subjective method of observing function, and that this should be adequate in discovering and estimating the divergences from the normal. However, this is not the case, pathology having led us to consider and investigate not only the function—that is, disfunction—but its physiological antecedents, metabolic, chemical, etc., and many side effects and issues besides; and finally, or let us say before all else, the structure of the brain as well.

Physiology.—Hence we keep in mind the anatomical brain, both gross and microscopic, and, not being able to examine it *in vivo*, infer from the anamnesis and clinical abnormalities present whether real substance injury has occurred.[1] We then consider its cellular activity, *i.e.* its physiology, its metabolism: besides the cell assimilation and catabolism (which allows of no direct inspection) there is the blood flow to and from the cells, bearing nourishment and excretion, endocrine substances (which may be food, specialized stimulant, or anti-autotoxic, but at all events a necessity), and at times endogenous or exogenous chemicals, toxins and ptomaines, etc. (from food, drugs, beverages, intestinal, fatigue and disease products),[2] defensive ferments, antibodies, and finally, secretions elaborated in the brain cells themselves (an internal secretion?), cholesterin, etc.

Psychophysics.—Still another cellular activity is postulated, and this actually essential for our comprehension of mind, namely, a biomolecular activity producing *energy* and accumulating it to tension, with subsequent discharge on sufficient stimulation. The discharge produces *electrochemical changes* which, when intense enough, give us our subjective phenomenon (consciousness), and are in some way accountable for the "neural" or "neuropsychic flow," that something sparking through the nerves, coursing from the periphery and end-organs to the cortex and efferently out again into the muscles. This, too, is the psychodynamic force in the brain affecting the *associations*, and thus combination and the continuity of thought.[3]

Concomitant with this accumulation, tension, and discharge of energy, or rather dependent upon it, are our feelings of well-being, fatigue, and exhaustion.

But for our feeling components themselves, and the finer shadings of feelings which make up our moods, Ziehen ("Physiol. Psycholog. d. Gefühle und Affekte," Sonderabdruck, Leipsig, 1903, pub. by F. C. W. Vogel) offers the theory that they are due to, are identical with, not the discharge, but the explosibility or readiness to discharge (*Entladungsbereitschaft*) of the cortical cells. A perception or a memory is due to a change in the cells (let us say a chemical change). The readiness with which such change occurs may vary; that is, the ability, the disposition to propagate such excitation (the chemical change) out of the cells and along the nerves may be greater or less. A greater readiness to discharge corresponds to positive, a lesser to negative feeling processes. But what determines the explosibility is not known.

The energizing activity is far greater in some cells (cortex, centers), less so in others. Possibly consciousness and awareness are awakened when its potence is high; none where it is low. Or, it may be that the phenomenon of consciousness is developable in specialized cortical cells only.

Its engendering source are stimulations from without, stimuli to the periphery no doubt detonating stored-up tension in the receptive cells of the end-organs and starting electrochemical changes (the neural flow) afferently to the cortex. Here it is received (perceived) and, after psychical elaboration, reinforced through added cortical energy and discharged efferently, to terminate in expression, motor setting, action, or deed.[4]

It is in connection with this *psychical elaboration* that the tangles and pathologies of mind occur, and this, therefore, the field of phenomena with which our probing is so immediately concerned. The facts to be considered are perception, memory, tonal feeling, and the association of ideas, the mind through this operation transmuting the entire sensory income into dynamic force or discharge.

The Mental Process.—The process may be described briefly as follows: While the peripheral stimulation continues (whether to ears, eyes, nose, tongue, skin), the cells in the cortex that are activated are conscious and we perceive (*i.e.* per-

ception); directly the stimulation ceases, the conscious phenomenon ceases (perception is at an end). But something has happened in the ganglion cells thus excited, a trace of something has been left behind, a deposit or "residuum" formed, which thereafter remains in the cell, dormant and *revivable*. This "residuum" is memory, and when re-excited we consciously recall—we remember.

It is assumed with probability (Ziehen) that the cells which are activated in perceiving are separate and distinct from those cell complexes which, after the perception, retain the memory images (the concepts, ideas), and that these latter cell groups form the association fields or areas (Flechsig) in which ideation proper—*i.e.*, association of ideas—takes place, and whence the impulse is finally sent into the motor cortical area, if such impulse is to be sent (as in acting or doing, etc.). The excitation must extend from the perceiving cells to the association field before recognition occurs. One does not recognize merely by perceiving. If the fibers between the former and the latter cells are destroyed, or the latter cells themselves, then we perceive but do not recognize, do not remember (*i.e.* aphasia). The association fields need not be thought of as localized in one definite spot. Possibly cell groups in various localities of the cortex are brought into play for this purpose.

Associated in some way with the process of perceiving is a feeling, agreeable or disagreeable, of pleasure or displeasure, positive or negative. We speak of it in psychology as *positive* and *negative tonal feeling*. But not only are we affected positively or negatively while we perceive, but the memory of this tonal feeling is retained in the cortical cells—awaking with the memory to which it belongs whenever the latter is reactivated. We have, then, the memory of a thing (concept, idea) and the memory of the tonal feeling connected with it.

Tonal Feeling.—Possibly the tonal feeling is a part-deposit of the memory "residuum." Possibly, however, the memory of the thing (idea) and its tonal feeling may be stored in two different *layers* or sets of cells. The latter fact seems tenable inasmuch as the tonal feeling is occasionally brought to mind alone, or before the memory to which it belongs is recalled. Thus it sometimes happens that we pass some one whom we recognize and who affects us with a peculiar tone, let us say an agreeable feeling, and whom we nevertheless cannot for the moment place. Only later does the connection dawn upon us. So perfumes frequently are agreeably "reminiscent" an appreciable time before the person or place with which they are associated comes to mind. That tonal feelings may become entirely disconnected from the memory-content to which they belong, get lost, as it were, or last on (well into life) after the content has passed into oblivion, is more than probable. Many of our strange feelings, intimations, and "vague reminiscences" are possibly due to this.[6]

The tonal feeling may also be *reflected* to other associated concepts, or be *irradiated* to events which follow. As examples of the first, we may be disagreeably affected by the very name of a town because something disagreeable happened to us there. We now abhor the town, and its very name, too. Or we like a place and everything associated with it because some one whom we are especially fond of lives there. As examples of the second, bad news in the morning may make the whole day "glum." Or we have occasion to get angry because something goes wrong, and for hours after we flare up at everything and everybody about us, kick the dog, slam the door, fuss over the food, mutilate an unoffending cigar, and curse things generally. If the affectivity of the occasion is strong enough, the tonal feeling may be projected into all we do and experience, and for days or weeks. So the optimistic effervescence when in love and the gloom during a period of loss or failure. Or again, we dislike some one, and because of it cannot help but valuate negatively everything he does. (In this instance there is both reflection and irradiation.) The great importance of this tonal feeling as a really vital force may be judged from the fact that the majority of our perceptions and memories reflect and irradiate their feeling to associated perceptions and memories. What we term moods are the resultants of such irradiations.

We come upon strong reflected tonal feeling in yet another connection, and this, in fact, so frequently in mental pathology that it must always be thought of. For instance, a man has an intense dislike, or even terror, of going into a rowboat, or any boat, or out upon any body of water. The reason for this does not lie in the boat or water itself, nor in the momentary state of affairs, but in a past affective happening, a shipwreck, the shock of which made a lasting impression upon the man. The momentary state, therefore, is conditioned through special *constellation*—namely, the shipwreck.

It is quite possible that one may be strongly affected, positively or negatively, through constellations the incidental facts of which need not even be thought of at the time; occasionally even be entirely forgotten.

When an individual's momentary state (opinion, feeling, point of view, etc.) is strongly surcharged through some former *affective* happening or series of happenings, we say he has a "complex." Here, too, the tonal feeling is conditioned through special constellation.

Neither the positive nor the negative need be pronounced; often the feeling-tone is at the threshold, as it were—neither above nor below.[7] But usually, when we are concerned, anxious or interested, it has a definite potence one way or the other, and may even be remarkably strong. It is the tonal feeling that plays the deciding part in the function of will, and is likewise, and especially so if intense or pathologically accentuated, the momentum, as we shall see, in the constraining, coercing, and emotional interplay of mind.[8]

Association.—Between the ganglion cells or cell groups there are interconnecting nerve fibers. In the association of ideas several cell groups are stimulated at the same time and their linking filaments traversed by the neural or psychoneural flow. These filaments from now on prove paths of least resistance, and should a stimulation again come to one group the excitation will overflow and course down these once utilized tracts as fluid down a groove. Just touch or skirt one group, and an-

other is short-circuited into action. Smell the perfume of a rose, and, though you see nothing, "rose" is associated. Some one calls you on the phone; directly you hear the familiar voice you associate the person. You cannot, in fact, think of the voice without the association of its bearer. These, of course, are simple associations, and closely related. Take a somewhat more complicated example: The parts of a jingle or nursery rhyme have no special association until you learn it, and then it spins itself out from beginning to end. You start your phone number, and then automatically rattle it off. You get a tune, and it "sings itself" out. These are all cell or cell-group combinations, the interjoining pathways of which are well furrowed.

The brain is filled with such nerve channels along which the electrochemical charge must displode. Hence the phenomenon of an excitation with predetermined reaction, that is, ideational reaction, the ideas running off in series of *wonted* associations. There may, at times, be several possible paths of discharge. The path chosen is determined by the momentary constellation or a larger background constellation. The *association test* is founded on this. If affectivity constellates the momentary choice it may be pleasurable or displeasurable, and may be affectivity of any kind. The former Jung (Freud) theory that it is usually unconsciously sexual is erroneous, and has for the most part been discarded.

But we must distinguish two such processes—on the one hand that of ordinary thinking, *i.e.* a purposively pointed train of thought, or a similar series of associations ending in action (voluntary action), in all of which certain links may be intimately and automatically joined, but in which for the most part new combinations are essential—a breaking up of associations and recombining—necessitating varying amounts of effort and attention and a balancing or outbalancing of tonal feeling with a final summation of positives or negatives determining the action or the goal of thought—and on the other a kind of thinking that must be sundered from the above, namely, ideation that is almost wholly automatic and nearly as regular and constant as a simple reflex.

In order to make this latter clear, let us for a moment examine voluntary action and differentiate it from the ordinary reflex. In the former the afferent excitation after reaching the sensory cortical area is relayed into the association field and there modified (recombination) by past memory images (*i.e.* association of ideas, ideation, "play of motives," thinking) and finally—after a winning out of either positive or negative feelings resulting in the *to be* or *not to be* of the action (in our case the positives winning)—shunted into the motor cortical area and thence into the actual movements constituting action. Attention, effort and awareness accompany the process, and the greater the work of combination necessitated, the intenser the attention, effort and awareness. Such action, finally, is appropriate to the occasion, conformable to the object in view. Hence all such voluntary acts are individual, specific, never alike.

If in the above process you omit the first (afferent) and last (efferent) links, you have the function of thinking or reflection.

In the simple reflex act (as in being startled on hearing a sharp noise), the excitation from the sensory cortical area passes directly to the motor without traversing the association field—and thence out into muscle reaction. There is no modification through memory images, no attention, no effort; it is not determined through tonal feeling and awareness plays little or no part. Such reflex is not specific to the occasion, but general and always much the same.[9]

In the phenomenon of automatic ideation alluded to, there are elements of both these types of action. The afferent excitation is decidedly modified by past memory deposits before it is efferently discharged, therefore must pass through the association area. But the path taken is so thoroughly trodden, so well grooved, that no new avenues or bridges must be built (no work of combination), and the entire process runs off fleetly, one might even say precipitously—hence without effort, with little or no attention and an awareness that may be negligible or nil. Besides, the end result, whether thought, word or action, is always the same. It is ideation, a train of thought, but one that coursing over a least resistance route and regularly over the same, has become swift, uniform, and, for the most part, aware-less—*i.e.* reflex.

Thus are explained many of our modes of expression, our peculiarities in speech, thought and action, our crotchets, idiosyncrasies, dogmatic points of view and judgments, the theories we harp on, opinions that cannot be changed, mental tilts, dispositions, etc., and here, pathologically, one must add the "idées fixes," stereotypes, the insistence of many a delusion or abnormal or insane thought, etc., etc.

Automatic Acts.—Still another type of association occurs, between ideas and actions or series of actions; many of our acts at first learned consciously and with difficulty later lose their awareness and, once started, functionate automatically. Thus our walking, climbing stairs, dancing, skating, writing, washing, dressing, shaving, eating, swimming, playing musical instruments, using a typewriter, etc. These are the really automatic acts of the literature.[10] They may run off without any consciousness or voluntary (conscious) and automatic acts may interplay and alternate. Such sequences may be quite complicated, yet accomplished with scarcely any awareness, as the daily going to business or office, etc. Even wonted occupations are for the most part plied automatically—sweeping, tidying up a room, cooking, knitting, spinning, sewing, linotyping, dispensing drugs, etc.

We may have an *automatic* association, then, between ideas and ideas, between an idea and an act, between whole sequences of acts, the associations at one time having been consciously acquired, now running off without consciousness. They represent a great saving of central energy and expedite immeasurably the mental business. They are usually of benefit to us—but under certain conditions may be the reverse.[11]

The Conditioned- Association- or Psycho-reflex.—Far more important for us to keep in mind is still another type of association which occurs and may continue on with strong persistence. A person crossing the ocean has a stormy voyage and gets seasick. On a subsequent trip, though there is no storm, in-

timations of sickish feelings may continue to come and may be suppressed only with difficulty. More sensitive individuals may even be strongly overcome. (Thus far we are dealing with ordinary association only.) But it is quite possible for such an individual to get seasick on the mere inspecting of the ship (let us say in engaging a cabin) by the smell of oil and cabin odors, having once had his seasickness intensified by the presence of these odors.

Analyzing this last instance, we find that the ship's movement was originally the real cause of the seasickness. But a second stimulation was *acting at the same time,* namely, ship odors. This is an associated stimulation, which, though in itself not causing seasickness, subsequently, we see, is able to act precisely as the direct stimulation.

This brings up the discussion of a psychological mechanism, already fairly well known in Russian and German medical literature, but almost entirely, if not wholly, neglected in our own,[12] namely, the "conditioned" and "association reflex" or "psychoreflex" of Pawlow[13] and Bechterew.

Both reflexes depend upon the principle that if you have two (or several) stimulations *active at the same time,* one of which causes a reflex activity, the other, even if in itself incapable of producing the reflex, will, after a time, because of the temporal association, likewise be able to do so. For example: if you place food in the mouth (of animal or individual) it acts as a stimulation to the local nerves, the impulse traveling thence to the central nervous system and from here out again into the salivary glands. Thereupon saliva is secreted. This is an ordinary reflex action (termed by Pawlow "an unconditioned reflex"), occurring even in animals wanting the higher centers. Now, if (experimentally) one, let us say, rings a bell every time the animal is fed (every time the unconditioned reflex is functioning) it is found that very soon it is possible to induce salivary secretion by ringing the bell alone. In the latter case we have, according to Pawlow, a "conditioned reflex" and to attain it the higher centers are necessary.

As an everyday instance we may take the phenomenon of "making the mouth water": if hungry, the smelling of food (or mere thought of it) produces a salivary flow. Here nothing is in the mouth, there is no direct stimulation. But the former associations (retained in mind) of appetite and secretion of saliva occurring in connection with the eating of food are now reactivated through the association of smell, or a mental picture, and the salivation occurs psychically.

Bechterew approaches the problem a little differently.[14] It is chiefly through the *motor reactions* of an individual, he says, that we can determine his relationship to the outer world. Hence the importance of motor reactions. Thus Bechterew has worked with the motor instead of the secretory apparatus, and speaks of the reflex obtained as the "associated-" or "psychoreflex" (instead of the "conditioned"). His studies are possibly more far-reaching than Pawlow's and his deductions of special moment for us.

Experimentally, Bechterew irritated a dog kept quietly in the dark by making a sharp noise. This calls forth an inspiratory reaction in a dog. Simultaneously, each time, a light was flashed (which causes no inspiratory reaction). After a number of "irritations," the light flash alone produced the inspiratory reaction. This the "association reflex." Later on, an electrical irritation applied to the dog's paw was used instead of the sharp noise and a bell rung instead of the light flash. Thus an "association reflex" of the dog's paw (a contraction) was easily obtained, and through other irritations was modified, inhibited or enhanced. In fact, so exactly can this be accomplished that the dog differentiates between several sounds, if several are used, neglecting all save the one employed for the association reflex (and can differentiate up to one-seventh of a tone).

It is not possible to give an account of Bechterew's experimental work and conclusions in greater detail here. It may, however, be mentioned that he found he had an exact *objective* method and criterion of determining the sensibility of a perceiving organ, of its anesthesia or hyperesthesia (or of a part). When a special center was destroyed in the cortex of a dog, no association reflex could be obtained. Nor was it possible to do so on the paralyzed side of a hemiplegic. Upon this ground Bechterew used the method for the examination of simulation and found it serviceable.[15]

For Bechterew the "psychic" process is only a more complicated form of the "nervous" process; hence he prefers the word "neuropsychis." (Cf., what I have already said of the "neural" and "neuropsychic" flow.) This may make it easier to understand Bechterew's dictum that the "psychoreflex" is only a more highly organized form of the ordinary nervous reflex. The difference between the two is that the latter is hereditary (phylogenetic), "the result of a whole series of former biological generations," and the former ontogenetic, representing personal, or earlier experiences of the individual, *i.e.* depending on individual experience and training.[16]

These psychoreflexes are termed by Bechterew, according to their outer manifestations, offensive, defensive, concentrative or preparatory (Vorbereitungs), emotive, mimic, symbolic, and personal psychoreflexes.

Studied on human subjects, the following is a simple instance. A sudden, loud noise makes us start, *i.e.* draw together. This is a mere reflex act of our organism and occurs not only in an adult, but in a young child too. If the loud noise happens to be the roar of a lion, we not only have this "startle" reaction, but we take to our heels. Nor is this mater first reasoned out; the individual thus suddenly affrighted reacts by running quite as automatically as the child "startles." If the latter knew nothing of a lion or the dangerous nature of this animal, it would not be frightened by the roar (save by its loudness); it would not run off like the adult.[17] The adult reacts to his gathered "associations" of lion—and this reaction is an "association"- or "psychoreflex."

Should the individual, instead of running away, face the emergency and prepare for defense, this series of actions is also dependent upon past individual experiences (memories and modifying associations) and represents a more complicated motor reaction—a purposive reaction—but yet an association reflex. Still another illustration: One turns aside and throws up a defensive hand if the barrel of a gun is pointed at one. The inexperienced child

will not react this way. (The above are the paradigms of Bechterew.)

Therefore, given certain antecedents, we more or less closely apprehend how an individual will act under certain conditions. Reversely, we may judge (and this is Bechterew's method—his *objective psychology*) of an individual's antecedent experiences by his actions. The child that fears the flame has had its lesson ("The burned child dreads the fire").

The importance of this teaching lies for us in its frequent applicability to the understanding of symptoms in neuro-psychopathy, as well as to factors in child development, normal[18] and abnormal—and, as I have already suggested,[19] may possibly throw light on the pathogenesis of many symptoms and pathological associations in hysteria.

We might also remember this mechanism in connection with the "complex" of Jung and the "constellation" of Ziehen just mentioned. By way of illustration, think of two individuals attending a socialistic meet; one is an anti and the other a rabid pro. Though the speech is the same, the impression carried away by each is very different indeed, depending upon his training, mental environment and economic and personal experience.

Let me cite some actual cases to show how these "association reflexes" may occur.

A child is late for school, rushes through its breakfast, feels extreme anxiety as to the outcome (scolding, humiliation, being kept in, etc.) and finally speeds offto school. After reaching there it vomits. On the following day, though there is no rush nor anxiety, through association of what happened the day previous, it vomits again. The child I have in mind was congenitally neurotic; the quite normal child would probably not have reacted in this way. And, in fact, we see these pathological association reflexes forming in individuals who are "sensitive," or ingenitely predisposed.

An adult patient attended the opera on one occasion after a bilious attack. He holds a seat in the first row of the dress-circle. On looking over the balcony he became so dizzy that he presently had to leave. The week after, this time not bilious, he attended the opera again and, looking over the balcony, thought of the dizziness he had had and, in a way, meant to test his own feelings. Suddenly he "imagined" (thus he expressed himself) that he was again dizzy and really felt so uncomfortable that he could not sit through the performance. This state of affairs continued until finally he had to give up this very desirable seat.

In a restaurant recently a friend of mine shuddered when I ordered oysters. A week before he had bitten into one that was "bad." It will no doubt be some time before he can brave another. I knew a boy who could not touch a fig; he had once eaten one into which a portion of a cigar stump had been pressed and had chewed upon and swallowed a bit before he could spit it out. The taste was so loathsome that the memory of it still nauseates him. Should one, in such instances, Freudean-wise continue the search until one finds or interpolates a sexual "complex"?

The following is a still more instructive example:

A neurotic patient was brought to me because of persistent vomiting spells, at first but occasional, later very frequent. She had been "pumped," lavaged, dieted, physicked, and treated with innumerable drugs. Nothing had helped. My analysis brought out the fact that the parents of the girl wished her to marry a certain man (considering him a fine match) who was physically offensive to her. The girl objected and the parents persisted. There were arguments, quarrels, scenes. The man was disgusting to her (the word Ekel which she used is not easily translated). One night he called and the girl felt nauseated. After he left she vomited. Expecting him the following evening, she vomited before he came. Thereafter she had vomiting spells every time the man was expected or called. Even thinking about him brought on attacks.

Here a psychoreflex had been established through the vegetative nervous system with the stomach, and every mental association linking in this man brought on an upheaval.

Let me also refer to a remarkable case mentioned by Oppenheim[20] in which a strongly constipated, hysterical woman could attain a movement of the bowels *only* when she gave caster oil *to her child.* Taking it herself had no effect whatsoever! Nor did any other purgative have any effect upon her.

Fear.—In connection with this mechanism of Pawlow and Bechterew, one must likewise bear in mind certain states of fear anchored into memory through some inadvertent association and continuing to function as a psychoreflex. One must even remember the possibility of fear being reflected or radiated to other concepts precisely as the tonal feeling already alluded to, for fear is a kind of negative tonal feeling in itself, a special, peculiar composite of feeling with accompaniments of physical commotion.[21] We all know the example of the child fearing the doctor, all doctors, and even anyone resembling a doctor; the very word "doctor" if used in its presence puts it on the defensive.[22] The fear of the "policeman," "boogie-man," and of the dark also belong here. The fear a mouse produces among a group of girls—even the cry of "mouse," the fear of bulls, ghosts, haunted houses,[23] etc., and, in fact, a considerable element in the mass reaction termed "panic," all may be explained as psychoreflexes.

Czerny[24] has given us an interesting study of fear as a conditioned reflex and his conclusions must be looked upon as important by both pedagogue and psychologist. Fear for him is a normal presence in the life of the normal child, it being a usual adjuvant in the process of training. Every adjustment to the milieu (community environment), even the simplest, requires the renunciation of certain personal liberties. Such renunciation, even under normal conditions, is not obtained without some constraining measures. Punishment is the most usual—and this always works through the fear of punishment, or the recurrence of the same, or its intensification. This fear has never been dispensable in rearing the child (and is found in the tenets of every religion). The fear of punishment is only acquired through training; this is the *acquired fear.*[25]

In the highly sensitive child, acquired fear is rapidly cultivated; in the normal with greater difficulty; in the abnormal (feebleminded) very late, or not at all. The normal child, therefore, has, and must have, the ability under certain conditions to experience fear. It is the duty of the educator to see that this fear is generated only for suitable purposes (expedience) and is not raised above a certain degree.[26] In this way the normal inhibitions are attained.

If one assumes that ten repressions will produce an inhibition in the normal child (this is taken merely as an example), then two or three are all that is necessary in the sensitive (pathologically sensitive or neurotic) child; besides, the inhibition in such cases is more intense and abides longer—sometimes indefinitely. Thus we also see that the

sensitive child casts off its acquired fear with greater difficulty. This necessitates the utmost care in the training of such children.[27]

The attainment of inhibitions, therefore, is one of the real factors in the training of a child. If wrongly applied, however, or applied to unsuitable children, it may lead to trouble, inasmuch as undesirable inhibitions will occur—and persist.

In conjunction with this mechanism let us finally not forget the immense power of *suggestion*, and in our mental probing look for the possibility of suggestion, or autosuggestion, playing a part. The mother says to her child, "You will be sorry if you don't do as I tell you," and, repeating this often enough, the child adopts the idea, in later life somehow holding to the thought, even if the parent no longer lives, acting just so, "for mother would not have wished me to do otherwise," etc. In delinquent and criminal cases this psychoreflex upon the basis of bad example or suggestion by actual word or intimation must always be carefully considered.[28] The preponderant influence of the milieu, the environment (home, folks, haunts, companions, etc.), also belongs here, and influences by direct suggestion or the autosuggestion through the seen example.

In leaving this chapter on association-reflexes let me comment on one difference between the reflex as experimentally attained in animals and as seen in pathological states of human subjects. In the former the reflexes are easily acquired, easily inhibited, and just as easily again uninhibited (the reflex thus again becoming active). In the latter, the association occurs chiefly but not always under affect, the greater the affect the greater the intensity; and, when once formed, the reflex is very tenacious indeed. It may be inhibited again through affect or need,[29] etc., and therapeutically through suggestion and counter psychoreflex.* The sensitive or neurotic individual is, of course, the more readily affected, and in this connection one may recall Oppenheim's pointing out that the nervous child forms habits with decided ease and loses them with very great difficulty.

It is possible enough that the beginning, the source, the cause of such a reflex may be forgot, yet the reflex still persist. Bringing the knowledge of such source or cause into mind will not, cannot logically, lessen the tenacity of the association.[30] Hence, the Freudean assumption that finding the root of the evil by psychoanalysis obviates the evil and thus cures the patient, must, from the viewpoint of psychoreflexology and the conditioned reflex, prove untenable.

Thus, to attain a finer psychical index of the individual, so to speak, after sifting the story that metabolism, blood and serum might tell, the inferences to be drawn from symptoms and signs, and the facts evidenced in the anamnesis, one must probe his feelings, associations and psychoreflexes—his psychoreactionability—and these in relation to his environment (home, family, friends, occupation, avocation, play and playmates) and to himself (past and present) and finally his mental tilt toward his immediate and more remote future (plans, hopes, ambitions, strivings, points of view). And in our scrutiny, where possible, we analyze present trends and dispositions in terms of past experience, and thus sound the soul for its depths and shallows, search out the sources of its potential currents, and pry up its buried life, its hidden caches of still smoldering impulses. This, to reiterate, is not therapy, but out of it a rational psychotherapy ensues.

*"The Land of the Blue Flower" by Frances Hodgson Burnett is a splendid story to be read and reread by children who have fear. It tends to give a direct counter psychoreflex to fear.

REFERENCES.

1. In which case we must consider focal destruction and compression of ganglion cells, axones and association fibers, and injury to distant cells and "centers" through destruction of connecting tracts (the diaschisis of Monakow).

2. Many of our chronic abnormal mental states (mental diseases) are due to secondary toxemias of a deranged metabolism. Beside intestinal mischief one must keep in mind the absorption from diseased gums, and possibly tonsils, and the severe anemias, the last occasionally leading to minute hemorrhages or miliary foci of damage in the brain. It should also be kept in mind that brain damage with mental alteration through minute hemorrhages, etc., may occur on disturbance of circulation dependent upon affectivity. In other words, organic brain changes may be occasioned through purely psychic causes. (See in this latter connection Bonhoeffer's "Wie weit kommen psychogene Krankheitszustände, etc., vor, die nicht der Hysterie zuzurechnen sind?" All. Zeit. f. Psych. Bd. 68, 1911, p. 375.) Some of the present war's shell shock cases appear to substantiate this.

3. "Perhaps the nerve impulse is something in the nature of a propagated explosive wave in a continuous substance. Whether that wave is in the nature of an hydrolysis or an oxidation we cannot say, but at any rate it results in the liberation, in some manner, of carbon dioxide. This substance tells us whether the nerve impulse has passed this way or not. The change which liberates it may be the impulse itself. Three kinds of changes occur, then, in our brains when the nerve impulses are passing—an electrical, a chemical, and a psychical change. Which is the fundamental change?"—A Chemical Sign of Life, Shiro Tashiro, Univ. of Chicago Press, Chicago, 1917.

The study of this entire chapter is termed Psychophysics. For the most thorough account and analysis see W. v. Bechterew's "Psyche und Leben," second edition. Wiesbaden, 1908.

4. With an overflow into the vegetative or autonomic nervous system entailing visceral and endocrine changes —these again occasioning afferent stimulation (and thus the subjective manifestation of emotion, affect, etc.). For a study of the vegetative system and the internal secretions in connection with mind, see our later report.

5. In Ziehen's psychophysical theory of feeling this may be the unknown causal factor behind the *Entladungsbereitschaft*.

6. See, for instance, Stendhal's "Souvenirs d'egotisme, Autobiographie" (Paris, 1892), and the study of L. Dugas, "Les particularités de la mémoire affective d'après Stendhal." *Rev. phil.*, 1916, 81 (digest in *Psych. Bull.*, May, 1917).

7. There are individuals who are characterized by this constant balancing of the negative and positive, neither strong enough to provoke a decision. We say they lack will and initiative. Hamlet is an example.

8. When tonal feeling is strong, especially where cumulative feeling occurs, one notices the phenomenon of the minds hanging on to such surcharged thought or constantly reverting to it. The slightest association may explode the thing at full strength. Just mention woman suffrage, or pacifism, or Freud, etc., to interested individuals and see what happens!

9. This differentiation thus far follows the teaching of Ziehen, but likewise accords with the views of Bechterew taken up below. The remaining points are not brought out by either.

10. It has been suggested that these automatic acts are localized in the optic thalamus. In "automatic ideation" the *grooves* appear to be cortical.

11. A special type of automatism occurs, in which the series of actions becomes dissociated from the ego, thus in nocturnal somnambulism, hysterical and epileptic automatic acts.

12. I have not come upon mention of this subject in our own medical literature at all; it has, however, been broached in the psychological; so, for instance, in J. B. Watson's "The Place of the Conditional Reflex in Psychology," *The Psychological Review*, Vol. xxiii, No. 2, March, 1916.

13. J. P. Pawlow, "Naturwissenschaft und Gehirn," Wiesbaden, 1910, Bergmann. The subject was taken up by Pawlow in an earlier report (which I, however, have not seen), "Vorlesung über die neuen Erfolge d. Naturwissenschaft," etc., Berichte d. Akademie St. Petersburg, 14, 1907.

14. W. v. Bechterew, "Über die Anwendung der assoziativ-motorischen Reflexe als objectives Untersuchungsverfahren in der Klinischen Neuropathologie und Psychiatrie." *Zeit. f. d. g. Neurol. u. Psychiatrie*, Vol. 5, 1911, p. 299. "Was ist Psychoreflexologie," Deut. *Med. Woch.*, No. 32, Aug., 1912; "Über dia Entwicklung der Psychischen Tätigkeit," *D. Med. W.*, Nos. 47 and 48, 1913. Raissa Golant, "Über die Motorischen Associationsreflexe," Ergeb. d. Neurol. u. Psych., 1 Bd., 3 Hft., 1912, etc. The first publication out of Bechterew's laboratory came in 1909. The phenomenon, however, I believe was noted and studied by him as early as 1907 or before. Thus it appears that both Pawlow and Bechterew started their work along these lines at about the same time.

15. It appears to me that this production of an association or conditioned motor reflex could be employed for diagnostic purposes in cases of hysterical anesthesia or paralysis and might prove a very important diagnostic measure, just as it has in the testing for simulation.

16. Ziehen gives an almost identical account. "Die psychologischen Probleme in der Heilkunde," *Zeit. f. aerztliche Fortbildung*, 8te Jahrgang, 1911, Nr. 1, p. 4.

17. It is interesting to note in this connection that the animals in Yellowstone Park, never being hunted nor harmed and always well fed, are practically tame. It is not especially unusual to meet a bear on a road; one gives him the right of way—and he wabbles on, scarcely noticing you. No psychoreflex of fear has been formed with you in the animal's mind—no psychoreflex of self-protection.

18. See, for instance, A. Czerny, "Über die Bedingungsreflexe des Kindesalters," *Strassburger med. Zeit.*, 1910, Hft. 9.—Bechterew himself points out some exaples: The infant at first cries and smiles reflexly, the first on hunger, the second on feeling satiated after feeding, or if some one tickles his cheek, etc. But very soon he also cries if the breast is withdrawn or the nursing mother leaves him; the smile or laughter is provoked on seeing the mother come in, etc. Still later he cries if a toy is taken away. Through his experience (new associations), he soon learns to differentiate between the mother and the nurse and reacts differently to each. See also N. Krasnogorski's "Über die Bedingungsreflexe im Kindesalter," Jahr. f. Kinderheilk., 69, 1, 1909. The last named follows the Pawlow school.

19. "Brain-tumor or Hysteria," MEDICAL RECORD, Oct. 7, 1916. This idea is already intimated in Bechterew's work, is also applied to the mechanism of laryngospastic attacks in children by J. Ibrahim ("über respir. Affectkrämpfe im frühem Kindesalter," *Zeit. f. d. ges. Neurol. u. Psych.*, 5, 1911, p. 407, et seq.), and is again brought up in K. Dessecker's dissertation on Hysterical Attacks, out of Goldscheider's clinic, 1914. J. B. Watson seems independently to have come upon the same idea (*l. c.*—p. 95, footnote), bringing the conditioned reflex in connection with tics and with hysterical motor manifestations.

20. H. Oppenheim, Lehrbuch, Berlin, 1908.

21. Plus changes in viscera and the internal secretions (cf., our subsequent report on the mind and the vegetative nervous system).

22. This fear is due to the child's sometime unpleasant experience with a doctor. But associations out of story books, or experiences in the home may form mental connection with the fear phenomenon.

23. The intense fear of cats in some individuals has as yet proven inexplicable. Such individuals may become so ill with fear—panicky fear—at the sight of a cat that they lose entire control of themselves. S. Weir Mitchell studied the phenomenon, but gave no plausible explanation. For the Freudean, of course, with his "symbol" prestidigitations, the thing is easy. It is interesting to note that there is no analogous dog fear. The person who fears a dog has either been bitten or frightened by a dog.

24. Ad. Czerny, "Die Enstehung und Bedeutung der Angst im Leben des Kindes," in Beiträge zur Kinderforschung und Heilerziehung, Heft 121, Langensalza, 1915.

25. There is also a born fear. This will be taken up in our third report (on Psychopathy).

26. Falling far short of the baneful habit of scaring a child with threats of the "boogie-man" or of "calling a policeman," or "getting the doctor," etc.

27. In the case of the feebleminded, fear cannot be employed in their training; one can accomplish something with them only through continued repetitions, often entailing infinite patience.

28. See W. v. Bechterew, "Das Verbrechertum im Lichte der objektiven Psychologie," Wiesbaden, Bergmann, 1914, p. 35-36; also my study of "The Degenerate," etc., *Archives of Diag.*, April-May, 1917.

29. A remarkably patent example of how an accepted custom (psycho-reflex) may be passingly abandoned (inhibited) through affect and need is shown in Guy de Maupassant's story of "Boule de Suif," in which the wonted disapprobrium of unchastity is temporarily nullified and such an act made a praiseworthy *expedient*.

30. Though this fact may be made use of in suggestive therapy, telling a patient, for instance, that the cause being come upon, the condition will now mend; or, again, using the knowledge attained in building up new associations—reeducation, etc.

60 WEST EIGHTY-FIFTH STREET.

MALIGNANCY OF THE BILIARY APPARATUS.*

BY WESLEY GROVE VINCENT, M.D., F.A.C.S.,
NEW YORK.
ASSOCIATE IN SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

FROM October, 1914, to the present time (March, 1917) about 22,000 patients have been admitted to the private rooms and wards of the New York Post-Graduate Hospital. During this same period there have been 15 cases in which malignant tumor of the liver was such an outstanding feature of the pathologic condition as to be made the principal diagnostic heading on the discharge card, and the same applies to 10 cases of malignancy of the gall bladder and one case of carcinoma of the papilla of Vater. It is thus seen that in about one in each nine hundred cases admitted to the hospital in the last two and one-half years the principal pathologic lesion has been malignancy of the biliary apparatus. This does not mean that during this period there have been but 26 cases in which malignant growths have been present in the liver, gall bladder, and bile ducts; for there have been many cases in which these structures, the liver particularly, have been involved by metastasis, but in which the discharge card merely records the site of the primary growth. The nature and location of the growths and the condition of the patients on discharge were as follows:

	Number	Cured	Improved	Unimproved	Died
Carcinoma of the liver	14	0	2	6	6
Sarcoma of the liver	1	0	1	0	0
Carcinoma of the gall-bladder and bile ducts	10	2	1	4	3
Carcinoma of the papilla of Vater	1	0	1	0	0

*Read before the Clinical Society of the New York Post-Graduate Medical School and Hospital, March 16, 1917.

It will be noted that but two of the twenty-six cases were considered cured when discharged. These were both early cases of carcinoma of the gall bladder.

Carcinoma of the Liver.—Primary carcinoma of the liver is rare; and still it is the most frequent of the malignant growths occurring in this organ. Of the carcinomata occurring in the liver a very small percentage are primary, nearly all being secondary to carcinomatous involvement elsewhere. Virchow found five cases of primary carcinoma in 6,000 autopsies. Hale White, in 10,000 autopsies found 10 primary carcinomata and 240 secondary to carcinoma elsewhere. Carcinoma of the liver may occur at any age, but is comparatively rarely seen before the age of 40. However, I would take this opportunity to call attention to the fact that, in general, we have not been sufficiently on the lookout for carcinomatous conditions in early life. For example, we are apt to consider cancer of the tongue a lesion of the middle or later decades of life; and yet including their own case, Gorse and Dupuich were able to collate 30 cases in which the age of the patient ranged from 10 to 30 years; while Castle finds that 42 cases of primary carcinoma of the liver in individuals up to the age of 16 have been reported. One case in this series, that of a boy 12 years old, occurred here in the Post-Graduate some years ago in the service of Dr. S. S. Burt. The youngest case was one day old and was reported by Noeggerath in 1854; another but three days old was reported in 1859 by Widerhofer-Wedel. While carcinoma of the gall bladder occurs much more frequently in women than in men, the opposite condition obtains as regards primary cancer of the liver, the proportion in the reported cases being approximately two cases in males to one in females; but secondary involvement is much more common in women than in men.

Pathology.—Primary carcinomata of the liver may be single or multiple and usually originate in the region of the gall bladder, the hilus of the liver or the bile ducts; rarely from the parenchyma cells. Lissauer inclines to the view, also held by others, that cirrhosis or syphilitic cicatrization is the primary affection and carcinoma development secondary.

Primary carcinomata of the liver occur in three forms: Primary massive carcinoma; primary diffuse or infiltrating carcinoma; and primary interlobular carcinoma. The description of these forms as given by Zeigler is essentially as follows:

In the first or massive form one or two large nodules are formed. These may occupy any part of the liver, but appear most frequently in the right lobe. The nodes are often of great size and consist of soft or hard white or slightly reddened tissue. At some points the tumor tissue is sharply marked off from the liver tissue, the latter being manifestly thrust aside and the biliary ducts and vessels compressed. At other points the tumor is continuous with the liver tissue, sometimes penetrating into the large blood vessels or bile ducts. The larger nodes are frequently softened or necrotic in the center, or contain extravasated blood. If the cancer is situated beneath the serous membrane, and a portion of the tissue in its interior is absorbed, an umbilicated depression forms on the surface of the nodule. In the course of time metastases are developed within the liver and the organ may thus become studded with numerous nodules.

The second, primary diffuse or infiltrating, form simulates the appearance of a granular or tuberculated cirrhotic liver, islands of whitish or brownish tissue being enclosed between stout anastomosing fibrous bands that traverse the organ in all directions. These islands consist, however, of cancer tissue and the condition is sometimes described as cancerous cirrhosis or cirrhotic cancer.

In the third, or primary interlobular, form the cancerous growths are seated in the interlobular connective tissue and wherever the portal vessels run they are seen to be accompanied by white tumid nodules in close mutual contact or actually coalescent, and varying in size with the size of the vessels.

In structure, some varieties of hepatic carcinomata are to be classed as cylindric celled adenocarcinomata; others as ordinary cancers of the simple or medullary type with solid cell nests. They originate either from the glandular cells or from the epithelial cells of the biliary ducts, the third form in particular being of the latter kind.

Metastatic carcinoma of the liver is most frequently secondary to carcinoma of the gastro-intestinal tract; more rarely of the uterus, pancreas, breast, or other organs. The growth starts from the carcinomatous emboli within the vessels. These embolic cancer cell nests multiply and force aside the liver tissue or follow the course of the vessels and pervade the parenchyma. The metastatic nodules may be few or exceedingly numerous and cases are met with in which the greater part of the liver is beset with miliary nodules. As the disease progresses these coalesce to form larger nodules. When the cancer nodules are large and numerous the liver is more or less increased in size, often enormously so, and its surface is uneven and tuberous.

Symptoms.—These depend largely upon the site, size and histologic character of the growth and the degree of involvement of surrounding structures. In the early stages of both primary and secondary growths there may be no recognizable symptoms. Even in well marked cases the sequence of symptoms is far from constant; for primary carcinomata occasionally reach a considerable size before any symptoms develop, while with metastatic growths the biliary symptoms may be so severe as to completely overshadow those of the original focus or, on the other hand, the liver involvement may not even be suspected during life and is found at autopsy. The usual symptoms are: Increase in the size of the liver, anorexia, cachexia, general weakness, vague digestive disturbances, jaundice, ascites, and a feeling of discomfort or actual pain in the hepatic region. Since the right lobe is the one most frequently affected the increase in the size of the liver, which may be considerable, is sometimes easily appreciated. Cachexia usually begins early and advances steadily and rather rapidly, particularly in the secondary cases. Jaundice occurs in at least 50 per cent. of the cases, usually begins gradually, but steadily increases in intensity and finally becomes very marked if the patient survives long. Occasionally the onset of jaundice is sudden and becomes

marked rapidly, while sometimes in the early stages the jaundice may for some time be slight in degree and of the intermittent type, later becoming constant and severe. Ascites also occurs in at least 50 per cent. of the cases, but varies widely in amount. Usually the amount is moderate; rarely excessive. When jaundice is present the ascitic fluid is bile stained; otherwise it is clear. Pain is seldom a marked feature in carcinoma of the liver. With deep seated growths there may be little or no pain. Marked pain may accompany involvement of the superficial portion of the liver with invasion of the capsule and consequent peritoneal irritation. Generally there is a feeling of discomfort or sense of weight in the hepatic region. When there is much actual pain it is usually due to perihepatic adhesions, with or without actual carcinomatous involvement of contiguous organs.

Diagnosis.—While vague symptoms perhaps referable to the liver may suggest the possibility of carcinoma of the liver, early diagnosis cannot be positively made without exploratory laparotomy. In the far advanced cases the combination of liver enlargement, progressive jaundice, ascites, cachexia and pain or persistent discomfort in the hepatic region make the diagnosis fairly evident. There is, however, a middle group in which, as in the early cases, exploratory laparotomy alone will make the diagnosis clear. Carcinoma of the liver is to be differentiated from amyloid and syphilitic liver and from hypertrophic cirrhosis.

The prognosis is very bad in any event, but without very early diagnosis and resection of the growth it is hopeless. In unoperated cases death usually occurs in from two to eighteen months, usually within six months.

Treatment.—Early radical operation offers the only hope of cure and in a few instances this has been obtained. Freeman, in 1904, reported a case in which he excised a nodular carcinoma and adjacent liver tissue and the patient was apparently perfectly well and with no sign of recurrence 16 months later. Schröder reported a case well seven years after operation and Roux has reported one successful case. A few other cases, at first apparently successful, died from recurrence from a few months to three years later. Castle has recently reported the first case of primary carcinoma of the liver in childhood in which the growth was completely excised. His patient was 10 months old and was operated upon by Jabez N. Jackson. The patient recovered from the operation, but died from gastro-enteritis shortly after leaving the hospital.

Sarcoma of the Liver.—Primary sarcoma of the liver is very rare. Knott, in 1910, could collate but 74 cases of primary sarcoma, but many metastatic cases have been reported. These are sometimes melanotic and due to metastasis from the choroid or following irritation and melano-sarcomatous degeneration of pigmented moles. The recorded observations show that sarcoma develops from the connective tissue in the hilum of the liver, from the fibrous sheaths of the larger vessels and bile ducts, and from the interlobular connective tissue. Nodules of varying sizes are formed within the liver, either singly or in large numbers, and these may give rise to sarcomatous metastases in other organs. Secondary sarcoma may consist of circumscribed nodules of large size, or of small disseminated nodules, or may infiltrate the liver in a diffuse manner.

The symptoms are similar to those of hepatic carcinoma. The treatment is practically hopeless, though temporary improvement may follow certain operative procedures and *x*-ray treatment. Aspinwall Judd controlled a case of this kind by *x*-ray treatment for some years.

Carcinoma of the Gall Bladder.—This is much more common than carcinoma of the liver. According to Deaver and Ashhurst it is found in about 5 per cent. of all cases of carcinoma, and the gall bladder is involved three to four times as often as the bile ducts. Among 3,908 operations on the gall bladder and ducts from 1890 to 1910, W. J. Mayo found 85 cases of malignancy. Bloodgood, in a series of 1,000 cases of gall-bladder disease at the Johns Hopkins and St. Agnes' Hospitals, found 60 cancer cases. Deaver found 6 malignant cases in one series of 262 operations, and 2 cases in another series of 159 operations. Erdmann, in a series of 270 cases of biliary surgery operated on between January, 1910, and April 10, 1914, had 4 malignant cases. *The prime etiological factor is gallstones.* Courvoisier found gallstones associated with carcinoma in 91 per cent. of the cases, Deaver in 87, Moynihan in 95, and Janowski in 100 per cent.; while W. J. Mayo, in an article on the prophylaxis of cancer, says: "In nearly all the cases of cancer of the gall bladder that we have had an opportunity to examine carefully gallstones were present or there was evidence to show that they had been present." He also states that cancer of the gall bladder occurred in nearly 3 per cent. of all the cases of cholelithiasis which came to operation at the Mayo Clinic. It is also interesting to note that in 2,538 cholecystectomies at the Mayo Clinic, papillomata not associated with definite cancerous lesions were found 107 times, and that Aschoff and Bacmeister believe that they are a predisposing factor in the development of cancer. Carcinoma in this situation may occur at any age, but in gerenal occurs later than carcinoma elsewhere, the larger number of cases occurring between the ages of 50 and 70.

Pathology.—The growth, which is of the cylindrical or epitheliomatous type, takes the form of a papillary or fungous tumor, or of a cancerous ulcer from whose floor start thickenings and indurations of the bladder wall due to neoplastic infiltration. From the gall bladder the cancer may invade the liver (nearly 50 per cent. of the cases), the gastrohepatic omentum and the duodenum. Carcinoma may also originate in the larger ducts, as well as from their intrahepatic radicles, and from the papilla of Vater. *Primary sarcoma* of the gall bladder is extremely rare, and according to Carson and Smith, who reported a case in December, 1915, only 10 well-authenticated cases are to be found in the literature.

Symptoms.—These are very similar to those of carcinoma of the liver, but in addition there is usually a history of gallstones. Practically all early diagnoses are made when operating upon the mistaken diagnosis of simple cholelithiasis or upon later microscopical study of the removed specimen. Taylor, summarizing the symptoms as tabulated by

various authors, finds that a dull pain referable to the region of the gall bladder is usually the first symptom, but that this pain may be referred to the stomach or appendix regions; that tumor below the liver is present in 50 to 75 per cent. of the cases, depending on the stage of the disease at which the case is examined; that jaundice was present in 69 per cent. of the 100 cases in Musser's series; that in Rolleston's series ascites occurred in 25 per cent. of the cases; and that among the complications may be rupture of the gall bladder with fatal hemorrhage, general peritonitis or general abdominal carcinomatosis; or there may be complete obstruction of the common duct, duodenum or colon.

Treatment.—Unless recognized very early, operation offers practically no hope of cure. In fact, it is generally recognized that when the affection has advanced to the stage when it can be recognized macroscopically, complete operative removal of all cancer nests is practically impossible; and the few permanently successful cases have usually been those in which malignancy was merely suspected at the time of operation or found after microscopical study in the laboratory. Mayo mentions seven cases of the latter variety and three of these patients were well three years after operation. In this connection W. J. Mayo says: "We have had no permanent cures after cholecystectomy for cancer of the gall bladder which had been diagnosed as cancer previous to operation. A number of cures have followed the removal of early cancer incidental to the removal of thick-walled functionless gall bladders, thus showing that it is not the nature or situation of the malignant process, but the delay in diagnosis which is so fatal." Bloodgood and Finney each had one successful case following cholecystectomy. Deaver advises that whenever possible, even in cases recognized as malignant, excision of the gall bladder, cystic duct, and the adjacent surface of the liver should be done. Certainly the removal of adjacent apparently healthy tissue is imperative; for when cancer of the gall bladder is distinctly recognizable at operation simple cholecystectomy offers but the faintest hope of cure. This is well shown in Terrier and Auvray's series of 16 such cases where there were 5 immediate deaths and the remaining 11 patients had rapid recurrences. If the involvement is not too extensive and the operation therefore too formidable, it is certainly justifiable to give these patients the bare chance that operation affords; especially in view of the fact that it is not always possible to differentiate at operation between inflammatory and carcinomatous infiltration, which accounts for the fact that a few cases have remained entirely well after drainage operations in what, at the operating table, appeared to be hopeless cases of carcinoma. On the other hand, drainage operations in non-carcinomatous cases have occasionally been followed by the development of carcinoma. Haggard and Willy Meyer have each reported one such case and Buchanan credits Graafe and Wiener with four.

Carcinoma of the Bile Ducts.—Primary carcinoma of the bile ducts differs from carcinoma of the gall bladder in a number of particulars. First, it is more frequent in men than in women, the proportion being about three to two; second, usually the first symptom that calls attention to the biliary apparatus is jaundice (Deaver). Most of the cases occur in the common duct or at its junction with the cystic and hepatic ducts. The growth is of the annular type or occurs as a papillary outgrowth into the lumen. The ducts above the point of constriction become dilated, and the same applies to the gall bladder unless previous disease has caused its contraction.

The symptoms are jaundice, which generally begins insidiously and gradually increases in intensity and which, when once established, is permanent; cachexia and rapid loss of strength; pain in the epigastric or gall-bladder regions, usually of a dull aching character, but occasionally colicky when the gall bladder attempts to empty itself; and enlargement of the gall bladder, this occurring, according to Courvoisier, in 84 per cent., and being palpable, according to Deaver, in 50 per cent. of the cases.

The principal condition from which carcinoma of the ducts must be differentiated is stone in the common duct. In this latter condition the jaundice usually occurs suddenly, is always intermittent, and the entrance of bile into the intestine is never permanently blocked. With carcinoma, on the contrary, once the passage of bile is blocked, acholia is permanent unless connection with the gastrointestinal tract is restored by operative means. The pain in calculous obstruction is sudden and severe and apt to radiate; while that of malignant disease is usually dull, dragging and persistent. Cachexia and rapid loss of strength would also point to malignant rather than to calculous disease.

Treatment.—This is one of the conditions whose cure really depends upon operation before the disease actually exists—that is, by the prophylactic early removal of gallstones. When the carcinomatous lesion is established, complete operative cure is almost impossible. The treatment employed is, therefore, usually palliative and consists in securing anastomosis of the gall bladder or dilated upper portion of the duct with some portion of the upper gastrointestinal tract, with or without coincident gastroenterostomy. The principles involved, indications for and character of operations employed for the relief of such cases in which there is chronic obstructive jaundice are well set forth in a recent paper by Erdmann and Heyd (*Am. Jour. Med. Sciences*, August, 1916), who report eight typical cases.

Carcinoma of the Papilla of Vater.—This is a rare condition. Deaver and Ashhurst, including those in Oppenheimer's tables, refer to 20 cases of transduodenal resection of the papilla of Vater, of which all but three were for carcinoma, and refer to three cases in which still more radical excisions have been made. Erdmann has reported two cases of carcinoma at this situation and cases have also recently been reported by Kammerer and by Tixier and Murard. The symptoms are those of interference with the flow of pancreatic fluid and the bile, together with symptoms of obstruction in the duodenum. The treatment, as already indicated above, is by excision if possible, together with provision for the reestablishment of the flow of bile into the gastrointestinal tract. In most cases gastroenterostomy is also required.

498 West End Avenue.

SOME OF THE NEWER METHODS OF TREATING WOUNDS.*

By FITCH C. E. MATTISON, M.D., F.A.C.S.,

PASADENA, CAL.

When requested by your program committee to prepare a paper on some of the "Newer Methods of Treating Wounds," I felt it was a task that could be done so much better by some of our members who have been at the front, and could give you their experiences in treating such wounds.

It is difficult for some of us to comprehend that in our age, when civilization has advanced to a point far beyond any that we know of, that any good can come out of the present conflicts; where weapons of destruction have become so mechanically perfect that the wounds inflicted by them are far more destructive, and conditions under which such wounds are made make infection almost certain, unless some benefits may accrue to mankind in the future by the necessity of the surgeon finding better methods in treating infected wounds.

It would be far beyond the limits of your patience to do more than mention some of the newer methods of handling such wounds. The present war has shown that sometimes necessity is the mother of invention, and when the soldiers commenced to burrow in the ground and sometimes were standing in mud most of the time wounds inflicted under such conditions were appalling. With clothing and their bodies covered with mud and trench filth, wounds under such conditions with splinters of shell, shrapnel, bullets, but especially pieces of clothing, were all infected. At first, such wounds were treated without regard for the possibility of tetanus, but it was not long before it became the rule to use tetanus antitoxin in all wounds.

In the Bradshaw lecture on "Wounds in War," Surgeon-General Sir Anthony Bowlby calls attention to the unfavorable conditions under which wounds are received. The country is thickly populated with human beings and supports many cattle and pigs; the soil is a rich loam, is heavily manured with excrements of men and animals; is covered by luxuriant crops; rainfall is copious; cloudy days are numerous, and every form of microorganism is abundant, and soil taken from a considerable depth below the surface bears pathogenical organisms. Men are covered by either mud or dust, and their comrades who help them are in a similar condition. Surgeon-General Bowlby speaks of the hypertonic salt solution of Sir Almroth Wright, and the use of antiseptics, and claims the object of each is the same in reality, for it is necessary for dead tissue to be disintegrated or cut off, and sloughs and granulation tissue to grow before healing can take place. He also states that one can appreciate more clearly now than ever before why the older surgeons spoke of "pus laudabile et bonum." "They understood that when velvety granulation and creamy fluid appeared destruction had ceased and repair had begun; and we recognize to-day, as they did, that there is such a thing as relatively healthy suppuration."

The following is the plan, on which all agree, when a patient is admitted to a line hospital:

1. Removal of infected bits of clothing, or other infected foreign matter.
2. Wide incision and drainage.
3. Immobilization.
4. Continuous irrigation by drop method with Dakin's solution of sodium hypochlorite; English surgeons as a rule seem to prefer Wright's hypertonic salt solution with the addition of citrate of sodium (sodium citrate 1 part, sodium chloride 4 parts, and water 85 parts), or continuous immersion in antiseptic solution of acetate of aluminum.
5. Continuous exposure of all wounds when possible to avoid foreign body reaction.

Many antiseptics were tried, but the most satisfactory one so far seems to be Dakin's fluid. The details of the preparation were worked out in the chemical laboratory attached to the Rockefeller Foundation Temporary Hospital 21, at Compiègne, and were published by Dakin in the *Presse Médicale*. After many experiments with a large number of antiseptic substances, Dakin made choice of the hypochlorite of soda, which has high germicidal properties, with the advantage of being the least harmful to the tissues.

The preparation of a solution of suitable strength for direct application to the tissues, that is, containing from 0.5 to 0.6 per cent. of hypochlorite of soda, is very easily made. One hundred and forty grams of dry carbonate of soda, or 400 grams of the crystallized salt is dissolved in 10 liters of ordinary water, and to this solution is added 200 grams of chloride of lime of good quality. The mixture is well stirred up, and after standing for half an hour the clear fluid is siphoned off from the precipitate of carbonate of lime, and filtered through cotton wool. To the filtrate, 40 grams of boric acid are added, and the solution thus obtained is ready for immediate use. The boric acid in this solution is not added for its antiseptic action, but for neutralizing the alkaline reaction, which in itself is irritating.

Dakin claims no credit for the "new antiseptic." He states that it was discovered by a French chemist, Berthallet, in 1788, and used for bleaching and disinfecting purposes, four years later, 1792. Percy of the Javel Works near Paris, made a similar fluid, and sold it under the name of eau de Javel. In 1820, Labarraque prepared a similar fluid which was known as Labarraque's disinfecting fluid.

This solution has been demonstrated by Alexis Carrel and his coworkers, Dakin, Dufresne, Dehelly, and Dumas, as being an energetic antiseptic solution, unirritating and of little cost. It should not, however, be used at the same time as alcohol, and must never be warmed. The solution should penetrate all crevices of the wound, and must be constantly renewed. After adequate drainage is provided, the solution is either forced into all portions of the wound, or the Murphy drip is used. The latter method has proven the most satisfactory.

Sir Almroth E. Wright's treatment of infected wounds by the use of hypertonic salt solution and vaccines, has met with some opposition from some of the surgeons at the front, and much of his work has not been correctly interpreted. He and his coworkers have worked out a very elaborate scheme for the phylacogogical treatment of wound infections. Briefly the scheme is:

*Read at a meeting of the American Therapeutic Society, held in New York, June 1, 1917.

At the First Aid Post after hemorrhage has been arrested, the wound has been cleansed, bandages, and splints applied, an injection of "antigangrene vaccine" is given. This is a vaccine containing the streptococcus, staphylococcus, and the bacillus of Welch. There would be, upon the inoculation, a rapid immunizing response, he claims, for all these wounds are infected, the predominating infection being the colon group. The most elaborate studies of these infections show that the clothing, bodies, and wounds of the men contain the colon group of bacteria.

Treatment in the field ambulance is: Washing and sterilizing, excision of projectiles and foreign bodies, procuring of efficient drainage, application of clean dry dressings, and injection of tetanus antitoxin. For the procuring of drainage, sufficient enlarging of the wound is made to permit of loops of sterile bandage previously steeped in a solution of 5 per cent. sodium chloride and 0.5 per cent. sodium citrate, these being carried down into the wound to serve as wicks. Previous to the introduction of the drain, the wound should be syringed out with the hypertonic saline solution. The ends of the wick are to be inserted between plies of lint well soaked in the same solution, and folded over so as to form a thick pad; one or two tablets of salt are planted in the dressing to keep the solution of proper strength when the lymph commences to flow, and over all an impervious protective dressing is placed. Wright claims that salt as a lymphagogue has no equal; 5 per cent. salt solution prevents clotting of blood, but not in the presence of pus, but the addition of the citrate of sodium prevents clotting of blood in the presence of pus.

Treatment at base hospitals consists of what he calls the full program of phylacogogic treatment. Cases of spreading infection, cellulitis, and gaseous gangrene are treated by free incision, supplemented by hypertonic salt solution until tissues are restored to their normal condition, and merely the surface is irrigated with a physiological salt solution until all surface infections are extinguished, then secondary suture of wounds, then irrigation with 5 per cent. salt solution or Ringer's or Locks' solution (without the sugar). The use of antiseptics and antiseptic precaution in all wounds is insisted upon.

Sir W. Watson Cheyne takes issue with Sir Almroth Wright on the latter's suggestion of the importance of serum for infection. Wright suggests that the main value of antiseptics is due to their production of a flow of serum. Cheyne also objects to Wright's hypertonic salt solution of 5 to 10 per cent., and contends that "brine," as he calls it, is good to preserve dead tissue, but is bad for live tissue. Cheyne makes a plea for the principles of Lister in the treatment of wounds, and contends that of late years, "A most unaccountable prejudice has arisen against antiseptics, with the result that students have not been educated in their use; indeed have been taught to decry their value and to look on them as old-fashioned and very objectionable substances." Cheyne recommends a strong antiseptic, Lister's strong mixture 1/20 carbolic lotion, to which is added sufficient bichloride of mercury to form also a 1/500 bichloride solution, in the early stages; but uses very weak antiseptics, if any, in the later stages. He has had no experience with Dakin's solution, but favors borsal (equal parts of boracic and salicylic acid), or a paste containing carbolic acid or cresol and borsal. A review of the controversy between the old Lister school as represented by Cheyne, and the school represented by Wright, which has possibly lost sight of everything but vaccines and hypertonic salt solutions, would lead one to take the middle ground between the schools.

Browning and his coworkers at the Bland-Sutton Institute lay down what they regard as the essential qualifications of a useful antiseptic. The bactericidal substance must have a great potency against all organisms in the presence of protein material, such as serum; it must be stimulating to granulation; it should have no delcterious effects on phagocytosis, no irritating action on tissue, and no toxic effect on the more highly specialized cells.

They found that a number of acridine dyes have an enhancing bactericidal power in the presence of serum and amongst these, the compound diaminomethyl-acridium chloride, which the authors, for the sake of convenience call "flavine," stands out foremost. This substance has been found to be 20 times more powerful than corrosive sublimate and 800 times more so than carbolic acid under these conditions.

Flavine and brilliant green are the two substances which hitherto have given the highest "therapeutic coefficient"; or in other words, the higher the germicidal power of a substance in the presence of serum, and the lower the effect in inhibiting phagocytosis, the more valuable that substance is as an antiseptic.

A practical formula for estimating the value of wound antiseptics, of arriving at their "therapeutic coefficient," as they put it, may be obtained by taking the ratio between (1) the highest concentration of the substance which does not reduce the phagocytic count below half that of the control, and (2) the weakest concentration of the substance which is sufficient to kill staphylococci in the presence of serum.

Delbit of Paris recommends a 12 per cent solution of magnesium chloride for irrigation, for dressings, and for subcutaneous injections. This fluid has over ordinary antiseptics the advantage of respecting the cells.

Rosenblith reports an analogous method. He had originally made use of magnesium chloride in the form of hypodermic injections of a solution containing in each c.c. 0.25 gr. of magnesium chloride and 0.02 of sodium iodide; later he used a stock solution prepared by dissolving 250 grams of magnesium chloride in one liter of boiling water. For use, 4 tablespoonsful of this are added to sufficient boiling water to make up to one liter, which is the normal solution employed at the Hospital Janson.

Dr. W. J. S. Ingram of Aberdeen, in deep infected wounds, uses silver nitrate stick very thoroughly and follows this by hot fomentations, and claims the wounds so treated clean up more quickly than after any method he has tried.

C. W. Duggan of Lincoln, England, uses equal parts of ichthyol and glycerine, this he applies with a camel's-hair brush, painting the surrounding skin as well as the wound.

The brilliant results obtained in the treatment of face and head injuries are due in no small part to some of the French surgeons whose patience and skill have won for them the admiration of the world, and when the history of this great European conflict is written, the French surgeon will share with the French soldier the praise they have so justly won.

When the surgeon of a few years ago had an ununited fracture or a comminuted fracture to operate on in a modern well equipped hospital, and got a satisfactory result, he felt justly proud of it, but consider the brilliant results obtained by some of the war surgeons, with badly shattered limbs in patients who are physically exhausted, with all conditions to make infection, and operating under conditions that are not ideal. Confronted with conditions such as they found, the surgeons had to meet difficulties such as are rarely, if ever, encountered in the usual run of hospital cases, where aseptic rather than antiseptic surgery is the rule, and where such wounds are taken to the hospital without delay.

Clinically the surgeons at the front who have paid close attention to thoroughly cleansing all wounds of all foreign substance, then rendering those wounds as free from infection as is possible, followed by thorough drainage by whatever means seemed best to them, have gotten good results; and if combined with all such means, a vaccine can be made for that particular case, we can all agree that the injured man is at least having all means known to science used for his benefit.

Capt. A. L. Lockwood of London has treated a large number of gunshot wounds of the knee joint along new lines. The cases he reports were admitted from two to five days following the injury. Where these is effusion, the joint is tapped and the fluid withdrawn to relieve tension, and if the fluid is blood stained or perceptibly purulent, he injects a 2 per cent. formaldehyde solution in glycerin (made up at least 12 hrs. before and not more than 7 days old), about 2 drams being used; or he employs ether and iodoform, pure ether, or 5 per cent. saline solution. The aspirated fluid is examined, the knee is immobilized, and screened or skiagraphed in two planes at right angle to each other. After it is determined to what extent the knee is injured, and the degree of infection, then the wound is excised *in toto*, and with another knife and forceps the capsule is excised, this knife and forceps being at once discarded; then, no necrotic tissue being left, and all foreign matter having been removed, all blood clots are irrigated out with saline solution. The capsule is stitched up, and drainage is made down to the capsule, but never in the cavity of the joint. Much tension is never allowed in the joint, but aspiration is made before tension becomes too great. Great care is taken in properly splinting all cases.

The points on which he lays most stress are: (1) That all foreign bodies, whether metal, loose bone, or clothing, should be removed from the knee joint at the earliest possible moment. (2) Perfect immobilization is absolutely necessary, do not start passive motion too early, wait at least three weeks after inflammation has subsided. (3) Absolutely complete excision of all necrotic or even edematous tissue. (4) The capsule should be closed at the first operation if at all possible. (5) Antiseptics other than those mentioned are never introduced into the joint. (6) Tubes should never traverse the joint surface.

W. Hale White of London calls attention to the low mortality of bullet wounds of the chest. According to Col. L. A. Lagarde, U. S. A. (Gunshot Injuries, 1914), the mortality of penetrating wounds of the chest in the French army during the Crimean War was 91.6 per cent., in the English army, over 70, and among those which survived to reach hospitals in the American Civil War was 62.5 per cent. But with the introduction of small bullets of high velocity, it began to fall. Thus in the Spanish-American War it was 27.5 per cent., in the Boer War 14 per cent., and among the Japanese in the battle of Mukden 3.67 per cent.; in the present war, although the mortality is low, it is probably not as low as the last figure.

Lieut. Col. A. Primrose, Canada General Hospital, does not favor Sir Almroth Wright's plan of treating septic wounds by applying a 5 per cent solution of sodium chloride and a 0.5 per cent. solution of sodium citrate, and applying a covering of "impervious protective tissue," as it hampers drainage by preventing a free evaporation from the surface and absorption into the dressing.

Col. A. W. Mayo-Robson contrasts the experience of treating gunshot wounds of the abdomen during the South African War, where it seemed to have been proven conclusively that opium, starvation, and rest in the Fowler position yielded better results than operation. His experience while serving in the Dardanelles, was that the wholesale expectant treatment was a failure. Where cases were seen late, and peritonitis had developed, he found that a small incision over the pubes, and the placing of a drainage tube, the patient being in the Fowler position, was the best treatment. He states that similar treatment is the best for typhoid perforation, as a good proportion of such cases are being saved in one of the large typhoid hopitals in France.

Dr. George W. Crile uses Winchester Doubouchet's method of treating wounds by the use of Dakin's solution and electric light. Crile uses bell-metal hoods or pasteboard cones. Electric lights are placed in these of a sufficient candle power to feel comfortable to the patient, and the results are very gratifying, infected wounds are exposed to the light without dressing, and wound secretions are cleansed with Dakin's or Wright's solution.

The writer has had very good results with this method, and especially in the treatment of extensive burns, and in skin grafting following burns. The wounds dry up very quickly under frequent cleansing with acetate of aluminum solution when there is too much moisture, or the use of Wright's solution to promote secretions when such wounds become too dry from lack of serum.

Dr. Rutherford Morrison of the Northumberland War Hospitals has used a paste composed of iodoform 2 ounces, bismuth subnitrate 1 ounce, liquid paraffin q. s.; any consistency may be made, but the most useful are those of soft butter or thick cream. All gangrenous and necrotic tissue is cut away, and the wound swabbed out with alcohol and a small portion (not to exceed 2 drams) is vigorously

rubbed into the tissue, a little being left in the bottom of the wound. No dressing is required for 7 to 14 days. He claims that (1) this paste maintains a continuous antiseptic action in the wound. (2) It acts as a lymphagogue and a free exudation of serum washes the wound from within outwards. (3) It does not prevent the escape of discharge. (4) Granulation tissue grows freely in contact with it. (5) Drainage tubes and gauze drains are unnecessary. (6) Septic wounds heal nearly as rapidly as non-infected ones. (7) Bone union is rapid and the tendency to form sequistrum is slight. Both constituents of the paste are toxic if absorbed freely, hence the use of more than 311 of the paste may prove toxic.

F. C. Lewis of the University of Liverpool produces hypochlorous solution electrically from hypertonic salt solution. He describes a very simple apparatus for its production from sea water and claims it is much more potent than the solution as ordinarily made, and wounds treated with the solution produced by electrolysis have given better results.

Sauerbruch, at the Swiss Surgical Congress in 1916, narrated his surgical war experiences in Germany, and is convinced of the necessity of immediate operative interference in all gunshot wounds of the abdomen, in which the peritoneum is involved, and believes that when this necessity is generally recognized, the arrangements for carrying out the operations will readily be improved at the front.

Dr. John O'Conor of Buenos Aires reports excellent results in the treatment of infected wounds by four-hourly irrigation with hot peroxide solution (2 ounces to the quart), followed instantly by hot carbolic acid lotion (½ ounce to the quart), followed by perchloride of mercury fomentations (wrung dry).

In going over the literature of the modern treatment of wounds, one is struck by the fact that there are two schools, or one may say factions. One which may be called the antiseptic school pins its faith on the use of some antiseptic, and there are many of these, with various combinations.

The other school, led by Sir Almroth Wright, the "Concentrated Saline School," depends for its success upon the fact that every precaution is taken to favor the rapid removal of all discharge from the wound by the hypertonic salt solution and a "salt pack." This pack, it seems, might be hurtful if one followed the directions by putting salt tablets in the dressings to be dissolved by the discharge from the wound, and in this way maintain the saline strength in the dressings. Might not such a "pack" act to dam back secretions from the wound, and prevent drainage? "Hot packs" of any sort, Dakin solution, hypertonic saline solution, or even sterile water, if such "packs" are changed frequently, not only facilitate drainage, but help to maintain adequate circulation and prevent lymph blocking. If any such hot pack be used and not used too long, drainage is facilitated. On the other hand adequate drains in a wound with a moderate amount of dry dressings that do not prevent drying of the wound quickly, are both rational and efficient.

Both schools agree thoroughly that all infected material must be removed from the wound, that drainage must be thorough and to all parts of the wound, and that such drains must drain the wound and not leave pockets; that drains, either tubes or gauze wicks, must be so placed that no obstruction is left to the free exit of secretions; that the antiseptic used must not be so strong that coagulation of the discharge takes place or irritation is caused; that, where practicable, wounds should be left open and not covered with thick heavy dressings that might by their saturation with the discharge act as a "pus poultice" and obstruct such discharge, clogging up lymph spaces, and favoring absorption rather than elimination of wound secretions.

The middle ground between these schools seems the most logical, as they both aim at the same ideals and for what surgeons have been striving for these many years, free mechanical drainage to all portions of the wound. If frequent irrigation of the wound by some solution that does not irritate tissue, and that is mildly antiseptic, will accomplish better mechanical drainage than will drainage tubes or wicks, such irrigation should be used, for war surgery differs from civil surgery only in so far as it is different in degree and character.

The handling of large numbers of cases under unfavorable conditions, necessitating prompt and efficient drainage, seems to have been met by both schools. They do not differ much in results. It seems to many of us that there are middle grounds between these schools that will prove of inestimable value; that the ingenious methods devised to procure adequate and prompt drainage, and to maintain such drainage until all infection has been removed, are used by all.

The selection of an antiseptic to be used in a wound is only one factor, but the way it is used is essential to its efficiency. Carrel claims that the rapid washing out of a wound with the strongest antiseptic and keeping the agent in contact with the infected area for a few minutes only, produces little or no results, and sometimes the application of strong antiseptics does harm rather than good. for if such agent produces coagulation of wound secretions or necrosis of tissue harm will result.

There are many problems in the treatment of wounds that are being worked out from a matter of necessity and so far it does not seem possible to use any of our present antiseptics in strong enough solution to sterilize wounds thoroughly by a few applications without producing either a coagulation of the wound secretions or necrosis of tissue, which favors bacterial growth.

The most effective way of treating such wounds is to use weaker antiseptics that limit bacterial growth, and do not irritate, but constantly cleanse the wound of all material favoring bacterial growth. The problem of reaching such wounds through the blood stream either by a vaccine or chemical agent has not been solved, but the downfall of autocracy may bring with it the downfall of the autocrats of wound infection, and although the price in human life seems appalling to us now, future generations may reap some benefits in the conservation of human life by the handling of wound infections.

Chamber of Commerce Building.

Salvarsan and Metasyphilis.—Le Pine is a pessimist on the use of the arsenobenzols in tabes and paresis. They are not only inert but actually injurious. Moreover a salvarsan cure does not always protect against tabes.—*La Presse Médicale.*

CESAREAN SECTION FOR ECLAMPSIA IN TWIN PREGNANCY, SAVING MOTHER AND BOTH CHILDREN.

By AUGUST SCHACHNER, M.D., F.A.C.S.,
LOUISVILLE, KY.

In view of the unsettled state that attends the treatment of eclampsia, coupled with a somewhat rarer feature of twin pregnancy and its successful issue for mother and both children, the writer deems the publication of this case a justifiable contribution to the subject.

The pathogenesis represents a fertile field still awaiting some patient investigator with the necessary time and perseverence to solve this obscure problem. As for the therapy, the writer is inclined to the belief that the quicker the uterus is emptied, the better, and the quickest way to accomplish this by means of a cesarean section.

The following extracts from McPherson[1] and Peterson[2] are instructive: "Regarding the frequency of the condition, 250 cases occurred in 14,899 labors, which means one case to every sixty labors, or 1.7 per cent. of all labors. This is a high percentage and is due to the fact that a hospital is the clearing house for so many of the cases occurring in the city, and the probability is that it is about eighteen times as frequent in hospitals as in private practice, the basis for this statement being that in our out-patient department, which represens private practice in 46,252 cases, eclampsia was encountered forty-three times, that is, one case in every 1,075 labors, or 0.09 per cent., as opposed to one case in every sixty labors in the wards of the hospitals, or 1.7 per cent. The condition is almost twice as common in primipara as in multipara, being 64.4 per cent in the former and 35.6 per cent. in the latter, which proportion is more nearly equal, however, than the figures commonly given. Multiple pregnancy is noted in this series in twelve cases, twins occurring eleven times and triplets once. In the series here reported, eclampsia was noted in the antepartum cases 140 times, or 56 per cent. In the postpartum cases eighty-six times, or 34.4 per cent., and in the intrapartum cases twenty-four times, or 9.6 per cent. Regarding the age of the patients, the youngest noted was fifteen and the oldest forty-eight years of age, the greatest number of cases occurring between the ages of twenty and twenty-five, which is in accord with the fact that the greatest number of eclampsias occur in primipara."

Frequency of Multiple Pregnancies in Eclampsia.

	Number of Cases.	Twins.	Percentage.	Triplets.	Percentage.
Esch	496	19	3.8	....	....
Glockner	147	9	6.1	1	....
Goedecke	403	19	4.7	1	....
Goldberg	81	4	4.9	....	....
Olshausen	200	16	8.0	....	....
Peterson (vaginal cesarean)	530	17	3.2	....	....
Peterson (abdominal cesarean)	500	21	4.02	....	....
Schauta	342	27	7.8	....	....
Zweifel	83	5	6.0	1	....
	2782	137	4.9	3	.13

It was found in the former investigation that the maternal mortality was higher among the multipara than with the primipara. In the 3134 collected cases it was 28.4 per cent., in the 771 multipara, while it was 22.35 per cent. or lower by 6 per cent. among the primipara. The age of the youngest patient was twelve and that of the oldest forty-six, the average age of 448 patients was 26.6 per cent.

The operative treatment of eclampsia has never been given a fair trial. To do this the uterus should be emptied quickly, as soon as possible after the onset of the first convulsion, not emptied after all kinds of medical treatment have been tried and failed.

Twins occurred twenty-one times in 500 cases of abdominal cesarean section for eclampsia or in 4.02 per cent. of cases. This is over three times as frequent as are twins in normal cases.

The maternal mortality in eclampsia after abdominal cesarean section steadily increases with the age of a patient, it being 23.63 per cent. between the ages of sixteen and twenty and 31.11 per cent. between the ages of thirty-one and thirty-five.

The mortality is distinctly higher after abdominal cesarean section in eclampsia if vaginal examinations have been made prior to the operations. The danger increases directly with the number of examinations made and the lack of asepsis employed. (Peterson.)

The following case was referred to the writer through the kindness of Doctors R. B. Scott and E. D. Whedbee:

Mildred B. (colored) age 19; occupation, housekeeper, primipara. Family history. Father died of asthma, age 48; mother living. Aside from the diseases common to childhood, she had never been sick. Menstruated normally since the age of 13 and continued so until interrupted by pregnancy in June, 1916.

Gestation normal until the eighth month when edema of feet and labia occurred. This increased until a week from the operation when the edematous labia reached a size as to interfere with the approximation of the limbs. A small amount of albumen was present in the urine when the edema began in the eighth month and increased to the time of operation, when large quantities of albumen were present. Eclampsia and premonitory signs of labor occurred simultaneously at the full term of gestation, March 12, 1917, at 7 A. M. For the control of the seizures the attending physician resorted to an anesthetic. The patient was removed to the Red Cross Hospital where the operation was performed. About noon, March 12, the writer assumed charge of the case.

Operation. Preliminary hypodermic of pituitrin was given just before making the incision. Gas ether anesthesia. Incision above the umbilicus and extending to about 5 cm. below umbilicus. The entire length of the incision in its stretched state was about 20 cm. This contracted to almost half after the delivery of the uterine contents and to fully half after recovery. The peritoneal cavity was in a measure protected by moderate packing around the interior circumference of the incision, together with a crowding of the edges against the uterine surface through pressure exerted by the assistant. An incision of hardly 15 cm. was made into the uterine wall with the membranes intact. The membranes were separated as far as possible from the uterine wall before they were opened. After as thorough a separation as possible, the membranes were opened and the children extracted by traction upon the feet with the delivery of the head last. This was carried out in each instance. Following the delivery, the separation and removal of the membranes was completed. The emptied uterus was almost outside of the abdominal incision, at least sufficiently so as to enable the closure of the uterine incision, outside of the peritoneal cavity. The uterine wound was closed with three layers of sutures. The first, No. 2, chromic gut,

including the endometrium and part of the muscularis. The second, a No. 4 catgut plain, involving the muscularis, and taking a liberal purchase with each stitch. The last, a serous stitch (Cushing) with No. 1 Pagenstecher. The wound healed primarily. The post operative course was practically uneventful, except for a mild rheumatic attack that occasioned some joint pain and a temperature curve varying from 99 to 102° F. During the first postoperative days, the breasts were inflated with air and massaged by Dr. Gary, who had employed this treatment in other cases and believed it to be of value. If any benefits attended the treatment in this case, they remained unobserved. The sex of the twins was female. The weight, 48 hours after the operation, was 2½ and 4 kilos, respectively, and at the time of leaving the hospital, almost six weeks after the operation, their weights were 5 kilos and 6½ kilos, respectively, or jointly almost double their weight at birth. There were five seizures on the same day following the operation, as follows: 3:40 P. M., 6 P. M., 6:45 P. M., 8:10 P. M., and 11:40 P. M., and four additional seizures the day following, namely, 2:45 A. M., 8 A. M., 11:10 A. M., and 1 P. M., making in all nine seizures after delivery.

The records show no seizures thereafter. At the time of writing, a little more than four months after the operation, both mother and children are doing well.

BLOOD IN THE STOOLS IN DUODENAL ULCER.*

By AUGUST J. P. PACINI, M.D.

NEW YORK.

WHEN a suggestively characteristic history is obtained the finding of occult blood in the stools warrants a confident diagnosis of duodenal ulcer. To be sure, in deciding the importance of the blood in the feces one must feel certain of having excluded that arising from food, from hemorrhages in other parts of the gastrointestinal tract, from hemorrhoids, and, in the case of female patients, from blood occasionally present in vaginal discharges which may become admixed with the feces at the time of defecation. It is a matter of no inconsiderable importance carefully to choose the test employed to detect the blood, and further rigidly to adhere to the detailed technique incident to whatever test selected. Adler's benzidine test has registered against it a few objections, but it embraces so many commendable features as to place it preeminently first in consideration. In this test, preliminary extraction of the stool with a mixture of alcohol and ether is a necessary requisite.

Fresh blood is readily detected, but blood which has undergone chemical change from physiological or pathological influences, or which has become most intimately mixed with the feces, may be so disguised or occluded as to render its recognition a matter of difficulty. In a series of thirty-two cases of duodenal ulcer wherein the clinical diagnosis was rightly confirmed at operation, routine benzidine tests were positive in twenty-six, or 81.25 per cent., and negative in six, or 18.75 per cent. of the cases.

The first case in the series presented unmistakable clinical and roentgenological evidence of duodenal ulcer, though the laboratory examination of the feces was negative for occult blood. It had developed in the history of this case that marked hemorrhages, and occasional tarry stools, had been noted at intervals of four or five months, some three years before, and while recurrence was not again observed, the acuteness of the present attack so simulated the previous ones attended by free hemorrhage that it seemed improbable that bleeding was entirely absent now. Accordingly, other tests were conducted, and included the guaiac (Van Deen's) test, spectroscopic examination for hematin, and microscopic search for crystalline blood pigments.

Common opinion, based upon established laboratory investigations, agrees in concluding that the benzidine is more delicate than the guaiac test. This was not possible to confirm in the short series studied. It is not denied, however, that in watery solutions of blood benzidine will react in dilutions with which guaiac has failed. In explanation of this apparent contradiction, the suggestion is tendered that, rarely, there is eliminated in the feces a substance which inhibits the benzidine though permitting the guaiac reaction for blood. As a precaution against occasional error revealed by this finding, it appears advantageous to conduct both tests upon the same stool.

If oxyhemoglobin is destroyed, as in the digestive tract when acted upon by the gastric or duodenal juices, a decomposition product, hematin, is formed. To this pigment is due the dark color of "coffee ground" vomitus in gastric cancer and the tarry appearance of the stools in some cases of duodenal ulcer. Arnold demonstrated three modifications of hematin, each showing a spectroscopic difference. These are acid hematin, neutral hematin, and alkaline hematin. Neutral hematin is without clinical interest. The differencce in the spectra of the acid and alkaline variety is distinct, and is recorded in standard text-books on clinical diagnosis. By noting the reaction of the stool to litmus it is usual to foretell the type of hematin (acid or alkaline) expected. Inspection of the tabulated findings will disclose that in two instances both the guaiac and benzidine tests had failed, but the spectroscopic examination revealed alkaline hematin (cases No. 1 and No. 28).

A striking observation which prompted this report was made in the last case of the series. Here the guaiac and benzidine tests had failed, the spectroscopic examination did not reveal any hematin, yet the microscopic search revealed occasional crystals of hemin; that is, hematin hydrochloride. These were identified with absolute certainty crystallographically. It is further noteworthy that the crystals were found in a stool which reacted strongly alkaline to litmus, a condition which adds to the complexity of the situation from a chemical viewpoint, inasmuch as the conversion of hematin to hemin is occasioned by the addition of hydrochloric acid. Anatomically, the ulcer at operation was located quite close to the pyloric ring, and it would seem that the conversion of the oxyhemoglobin to hematin, then to hemin, took place readily at that point high up in the gastrointestinal tract, and that

*From the pathological laboratories of the American Telephone and Telegraph Company.

the hemin passed unaltered until expelled with the feces, the alkalinity of the feces along the tract being insufficient to destroy it.

TABLE SHOWING CONDITION OF BLOOD FOUND IN FECES FROM THIRTY-TWO CASES OF DUODENAL ULCER, THE DIAGNOSIS CONFIRMED AT OPERATION.

Case No.	Reaction.	Guaiac Test.	Benzidine Test.	Hematin.		Hemin Crystals.
				Acid.	Alkaline.	
1	Acid	−	−	+	+	−
2	Alkaline	+	+	+	−	−
3	Alkaline	+	+	−	+	−
4	Alkaline	+	+	−	+	−
5	Acid	+	−	+	+	−
6	Alkaline	+	−	−	+	−
7	Alkaline	+	+	−	+	−
8	Alkaline	+	+	−	+	−
9	Alkaline	+	+	−	+	+
10	Alkaline	+	+	−	+	−
11	Acid	+	−	+	−	−
12	Alkaline	+	+	−	+	−
13	Alkaline	+	+	−	+	−
14	Alkaline	+	+	−	+	+
15	Alkaline	+	+	−	+	+
16	Alkaline	+	+	−	+	+
17	Alkaline	+	+	−	+	+
18	Alkaline	+	+	+	+	−
19	Alkaline	+	+	−	+	−
20	Alkaline	+	+	−	+	−
21	Alkaline	+	+	−	+	−
22	Alkaline	+	+	−	+	−
23	Acid	+	+	−	−	−
24	Alkaline	+	+	+	+	−
25	Alkaline	+	+	−	+	−
26	Alkaline	+	+	−	+	−
27	Alkaline	+	+	−	+	−
28	Alkaline	−	−	−	+	−
29	Alkaline	+	+	−	+	−
30	Alkaline	+	+	−	+	−
31	Alkaline	+	+	−	+	−
32	Alkaline	—	−	−	−	+

In conclusion, the following suggestions are submitted:

1. Blood in the feces is a finding of positive value (in this series it was present in every case in some form), when extraintestinal sources are absolutely eliminated, in cases of duodenal ulcer.

2. The examination should include the guaiac test, the benzidine test, spectroscopic search for hematin, and microscopic search for hemin crystals.

195 BROADWAY.

HENOCH'S PURPURA.

BY M. B. WESSON, B.S., M.D.,

EL PASO, TEXAS.

THIS case belongs in the group which Osler designated as "exudative erythema," and illustrates the difficulty of classification. The etiology is unknown. There were polymorphic skin lesions, edema, hemorrhage, arthritis, gastrointestinal crises, and acute nephritis. In July it would have been called peliosis rheumatica, but in September it was clearly a case of Henoch's purpura.

Onset was with subcutaneous nodules over hips in July, 1916, accompanied by rheumatism; these disappeared at the end of one month and were followed by gastrointestinal crises; then an asthma with rapid respiration and subnormal temperature developed; gonorrhea present. Urine contained 1 per cent. albumin, with fine granular casts; on September 5 a purpura developed; anasarca of feet, legs, and hands appeared, and death followed on September 23, 1916, from terminal pneumonia.

Miss M. H., age 21, normal weight about 140 pounds, cabaret dancer, no previous history of illness aside from operation in 1912 for removal of tonsils and adenoids. For the past three years has been a moderate user of alcohol. Denied venereal infection. She gave a history of the development on July 1, 1916, of a number of subcutaneous nodules about the hips. She stated that these were not stationary, but disappeared and reappeared and changed position without any apparent reason. When they were present, her knees were painful but not swollen, and eventually other joints became involved. All symptoms had disappeared by August 1, at which time gastrointestinal crises appeared, anorexia, pain, diarrhea, and vomiting without any reference to the time of food ingestion. Eventually, an asthma developed, and when I first saw her on September 3 she was markedly emaciated, not weighing over 90 pounds, and was sitting upright in a chair, having considerable trouble to get her breath—had not been able to breathe in a recumbent position for ten days. Her diet consisted largely of dill pickles and lemonade, she having been under the care of a Christian Science healer for one month. Her temperature was 95° F. (mouth), pulse 124, respiration 44.

Lung examination showed diffuse rales, an apparent hypostatic congestion of bases, with prolonged expiration at apices. Heart, point of maximum impulse visible and palpable in 5th I. S., 8 cm. to left of midsternal line; no murmurs and no accentuations. Abdomen was more or less rigid and painful to the touch, spleen not palpable, and liver edge extended to costal margin. No evidence of pyorrhea alveolaris. Sputum was difficult to obtain, never rusty, and contained no pneumococcus or acid fast bacilli. Vaginal examination: Uterus immovable and pelvic contents seemed to be matted into one mass; urethral smear negative, but uterine showed gonococci.

Urine (24 hr. spec.), 26 oz., amber color, sp. gr. 1020, acid reaction; no sugar, 1 per cent. albumin, few fine granular casts, numerous pus cells, no R. B. C.

Blood: Red cells, 4,640,000; white cells, 20,000; Hb., 85 per cent.; differential polynuclears, 87 per cent.; small lymphocytes, 3 per cent.; large lymphocytes, 3 per cent.; large myelocytes, 6 per cent., and transitionals, 1 per cent. Wassermann test was negative.

On Sept. 5, purpura developed on chest, which gradually extended to entire front of body and extremities; back not involved. Bowels moved daily, but after a thorough catharsis followed by strong enemas three full bed pans of feces were removed at one time.

Throughout the illness, the temperature ranged from 95° to 100° F., generally subnormal; the pulse ranged from 108 to 124, and the respiration 40 to 44.

The patient gradually improved under symptomatic treatment (arsenic, as suggested by Dr. Osler, was used in form of sodium cacodylate), but on September 18 a general anasarca developed and death occurred on September 23—due to terminal pneumonia.

The case is reported on account of the rapidity of progress and the question of the gonorrhea as being the etiological factor responsible, as there had evidently been a very malignant gonococcal infection which had spread to peritoneum and caused adhesion with resultant coprostasis and autointoxication.

212 ROBERTS' BANNER BUILDING.

The Tongue Signs in Pernicious Anemia.—Zimmermann refers to burning pains in the tongue, which not infrequently accompany this condition and to actual redness, fission and miliary vesicles, which are sometimes added. These phenomena have not been seen in other severe anemias. — *Muenchener medizinische Wochenschrift.*

Schauta on Irradiation for Cancer of the Uterus.—As a pioneer in the radical operation for uterine cancer Schauta is sceptical as to the wearing qualities of the new methods of treating this affection. He has treated eighteen operable cases with radium and has four "cures" after one year and one three-year cure, but seven patients have already died, while the others have disappeared. Radium is on trial. The idea of irradiation is popular with patients, and that is an advantage to be considered.—*Correspondenz-Blatt für Schweizer Aerzte.*

Military Medicine.

MEMORANDUM ON THE TECHNIQUE OF THE SUTURE OF WAR WOUNDS.

By CLARENCE A. McWILLIAMS, M.D.

CAPTAIN, M.C.R., U. S. ARMY HOSPITAL 15 (ROOSEVELT HOSPITAL), FRANCE; ASSOCIATE SURGEON PRESBYTERIAN HOSPITAL, NEW YORK CITY.

In a tour of the British hospitals of the Third Army, the conclusion was arrived at that no standard method of treating wounds had been reached as yet. Two principles had, however, won universal recognition: first, the earliest possible treatment of the wounds after their reception, and, second, the necessity of the thorough excision of the tissues of the damaged tract together with the missile. There seemed to be general recognition of the value of the Carrel method of treating wounds, but efforts were being made to overcome the difficulties of using the Carrel treatment, while the patients were en route to the base hospitals from the front, by the employment of various antiseptic pastes. The regimental aid posts are the first-aid stations, situated usually in dugouts in the second-line trenches. From this station the patients are brought along the communicating trenches to the advanced dressing station, situated in the cellar of some ruin, where more pretentious first aid is given. The patient then is carried in Ford ambulances to the main dressing station (a field ambulance), which has 150 beds. Here few operations are performed except those of urgency, such as the stoppage of hemorrhage. The main dressing station is situated from three to four miles from the trenches. Patients in severe shock are kept here until recovery from this is sufficient to warrant their removal to the casualty clearing station, which is located five or six miles from the firing line. This station has a varying number of beds, usually from 600 to 1000. This is where all operations are performed and missiles extracted, an *x*-ray plant being in immediate proximity to the operating room. The casualty clearing station immediately adjoins a railway track by means of which all patients are evacuated by trains to the base hospitals as soon as their condition warrants this. The treatment of wounds in Casualty Clearing Station No. 3 is as follows:

A. *Excision of the Wound.*—1. After sterilization of the skin, every endeavor is made to stain all the tissues of the wound tract or surface with a ½ per cent. solution of brilliant green or ½ per cent. methylene blue. The stained tissues render the thorough excision of the whole damaged area easier. In the case of a tract this staining is done by injecting the stain through a rubber tube closed at one end like a Carrel tube, and perforated by many very fine holes; at the distal end are two larger holes. Tubes perforated for a distance of 2, 4, 6 and 8 inches are used. A suitable tube is passed along the wound tract, if possible, up to the foreign body or fracture. No force must be employed in spraying the dye in order to avoid forcing it along intermuscular planes. In the case of a surface wound, a syringe and a mop are used. After two minutes the excess dye is wiped away. Hemorrhage prevents staining.

2. The wound is then excised, using the stain as a guide. A wide exposure of the parts is made, including incisions through healthy skin; an incision of 8 or 9 inches long to expose a fractured femur is frequently required. Whenever possible the whole of the tract should be seen and not simply felt. Damaged muscle does not twitch or bleed on being cut. All this should be removed, as gas gangrene occurs most frequently in damaged muscle, until the muscle twitches and bleeds on being cut. The excision proceeds from the skin to the missile, which is removed last, preferably wrapped in the tissues which surround it. Dirty bone is gouged out. Fragments of bone which are attached are not removed, only loose ones being taken away. Having regard for important structures, all stained tissue must be removed. The tissues and clothing around the missile ought to bear traces of the dye.

B. *Application of Paste.*—One of the first pastes was "*bipp*," which consisted of bismuth, iodoform, and paraffine. On account of a number of poisonings which have occurred after its use the army has recommended that it be given up.

The present paste in use has the following formula:

℞ Boric acid.....11 oz.
French chalk.....1 oz.
Liquid paraffin.....8 fl. oz.
Brilliant green.....17½ grains, *i.e.* 1-500

The boric acid and French chalk must first be intimately mixed in a mortar, then the liquid paraffin worked in, and, finally, the brilliant green, dissolved in rectified spirit, added. Considerable time and energy are required to avoid a paste with many isolated masses of boric acid. It is kept in jars and in large syringes with very wide nozzle apertures. A grease pump is useful.

As to brilliant green, the conclusions of an article in the *British Medical Journal*, June 30, 1917, p. 870, are: (1) Brilliant green is undoubtedly an active and efficient antiseptic. (2) It is non-irritant. (3) It acts well in the presence of serum. (4) It possesses very definite "auxetic properties." (5) It stains dead tissues green, and in this way may aid the surgeon in determining what to excise. (6) As it is soluble in "saline," it can be used in conjunction with the "salt pack." (7) It can be used after the method of Carrel.

Use of the Paste.—1. All bleeding having been arrested, the wound is dried throughout with spirit or 1 per cent. picric acid in spirit.

2. The paste is rubbed in as with "bipp" and it must be done with all thoroughness into every recess; five minutes ought to be so spent in dealing with extensive wounds. The syringe is used to bring the paste to all deeper parts before rubbing it in and later to fill the cavity. The deepest parts are treated first. Bone fracture areas must be packed with it. Sutures are occasionally inserted to bring together skin edges which have been divided by the knife. Dry gauze dressings are used. A paste made of the aniline dye flavine is also used and seems to be as efficacious as that of brilliant green.

C. *After Treatment.*—Where the case (1) progresses favorably the wound is not looked at until the temperature is normal in the evening, which usually occurs on the third or fourth day in wounds of soft parts. A smear count is then made; an average of 4 cocci per field should be the maximum for

suturing. If for any reason suturing is not advisable, the wound is repasted if that originally put in has disappeared.

2. Progresses unfavorably, the excision or pasting has been incomplete. Then further operative measures and repasting are necessary. The temperature may be slow in coming down, although the wound is clean. Here boric fomentations have proved of value.

D. *Suture of Wounds.*—Under an anesthetic the wound is wiped out and dried with spirit and the edges freshened. A very thin film of paste is then everywhere rubbed in and the excess wiped away. Silkworm sutures are inserted, some undermining being often necessary to close the cavity. Tension sutures have fine rubber tubing threaded in to them. There should be no tension in the skin, this being overcome by undermining. No drain except a minute one in some fractures is used.

A dressing is taken down only because of an unfavorable prognosis, for a count, or for the removal of sutures. A string scar usually results. Nitrous oxide anesthesia is occasionally necessary for deep repasting in the ward. Where the foreign body has not been removed, this treatment should not be followed. Abdominal and head wounds (primary suture), excisions of joints, etc., are treated in the same way.

Amputations.—All amputations in which flaps are cut (and the only exceptions are in some cases of gas gangrene) are pasted in the same way, the flaps being apposed by one or two sutures. Complete suture is done when the temperature is normal, fresh paste being applied.

Primary suture may be performed in selected cases of wounds of soft parts where a complete excision of damaged tissue has been possible.

The results of this treatment as I saw it seemed most favorable. Where a clean excision of all damaged tissues is done, one would expect a good result without the paste, although one could scarcely hope to obtain an absolutely uncontaminated wound. The object of the paste is to take care of infection of the wound coming from the damaged tissues during the excision. Excision of damaged tissues seems to be the one clear procedure which experience in this war has proved to be the most life saving with the Carrel treatment a close second. Whether some form of paste will take the place of the Carrel treatment in overcoming sepsis remains to be seen.

SANITARY STATISTICS OF THE AUSTRO-ITALIAN WAR.

BALESTRA has compiled some interesting figures, having both sanitary and military significance, which appeared originally in the *Giornale di Medicina Militare* and have been summarized in the *Office International d'Hygiene Publique* for August. A chronological division is made for purposes of comparison. The first period extends to Dec. 31, 1915, and the second from January, 1916, to June, 1916. Figures on morbidity are limited to hospital cases, although it must be understood that there was much illness in the ranks which was not deemed serious enough for hospitalization. The average daily hospital morbidity for the first period was 2.71 per 1000; for the second period, 1.57 per 1000. These figures seem particularly gratifying because the calculated morbidity for large units was 4 per 1000. The chief credit for this result should be awarded to sanitary prophylaxis. The figures for individual sectors show great seasonal and other variations and a definite idea of morbidity could not be obtained save in grand averages. The hospital admissions showed the following percentage distribution of diseases: Ordinary medical maladies, 58.81 for the first period and 66.81 for the second period; ordinary surgical affections, 12.49 and 17.80; endemo-epidemic diseases, 7.57 and 3.59; affections of the eyes, 9.06 and 4.44; venereal diseases, 9.05 and 4.62; scabies, 3.02 and 2.74. The reduced morbidity in the four smaller categories naturally raises the percentage of the ordinary medical and surgical cases.

Next in order come the figures for the wounded by character of weapon used: Artillery, 46.91 per cent. in the first and 54.74 in the second period; portable weapons, 52.60 and 39.16; side arms (bayonets, etc.), 0.36 and 0.59; gas, 0.13 and 5.61. A comparison of these figures with corresponding figures of the Russo-Japanese war shows marked differences. At the earlier period gas was unknown and the percentages of wounds were, infantry weapons, 80; artillery, 15; side arms, 5. In the Italian figures bombs and grenades are classed under artillery. The low percentage of sabre and bayonet wounds in the Italian service is readily explained by trench warfare, which has largely eliminated them, since the grenade does the work of the bayonet.

In regard to severity of wounds the serious injuries made up 31.60 per cent in the first and 23.62 in the second period; the figures for the medium wounds were 55.38 and 63.01. Finally wounds so slight that the victims returned at once to the ranks were 13.02 and 13.07. The site of wounds (head and neck, trunk and extremities) agrees with those on other fronts, the majority being in the extremities (64.3 and 56.4). The percentages for the head and neck were 18.4 and 21.92; for the trunk, 17.3 and 21.63.

In regard to mortality from wounds the figures for deaths on the battlefield were 5.47 and 7.87; for deaths resulting later from wounds, 11.24 and 10.16; totals, 16.71 and 18.03. These figures are much lighter than the calculated mortality of 25 per cent.

Care of the Tuberculous Soldier in France.—The organization for the diagnosis, treatment, and aftercare of tuberculous French soldiers is divided into four sections: (a) Special consultations. (b) "Centres de Triage." (c) Hospital sanatoria. (d) After care. Special consultations are held by the Army Medical Service from time to time to examine any soldiers thought to be infected with tuberculosis.

All soldiers suffering from tuberculosis, or in whom there is the slightest indication that they are likely to develop the disease, are sent to the "Centres de Triage," which are in direct connection with the above mentioned service. The examination of the men is there carefully carried out. Those found to be suffering from tuberculosis are sent to sanatoria established under the

direction of the Minister of the Interior. The Military Medical Service made an agreement with the Ministry of the Interior that no soldier should be discharged until he had received at least three months' treatment in one of these institutions. Thirty sanatoria have been established in various parts of the country. These are intended not only to afford treatment of the disease, but also for the education of the patients in the best way of caring for themselves and of preventing the spread of infection to those around them after they leave the hospital. A number of other institutions for the treatment and care of the tuberculous have been established by private enterprise.

In spite of all that has been done, however, the accommodation provided for the tuberculous soldier is lamentably insufficient. It was stated recently that there were more than 25,000 soldiers in need of sanatorium treatment for whom no place could be found.

Department Committees have been formed for the purpose of watching over the welfare of men discharged on account of tuberculosis. The Prefect of each Department is furnished with a list of men treated in the sanatoria, and on their discharge he informs the Department Committee. Then visitors, chosen as far as possible from the class to which the tuberculous person belongs, are appointed under the committees to go to the men's homes and find out what can be done to insure their living under conditions favorable to themselves and to their families.—*Recalled to Life.*

Health of the United States Expeditionary Forces.—Reports to the Surgeon General of the Army on health conditions of the American Expeditionary Forces for the week ending November 9 give the following information: The annual admission rate per thousand (the ratio of new cases of a disease which would be found per thousand men per year if the proportion continued throughout a year the same as during the period covered by the report) was, for pneumonia, 16.6; dysentery, 2.0; malaria, 1.0; venereal disease, 181.5; typhoid, 0.0; paratyphoid, 0.0; measles, 27.1; meningitis, 1.0; scarlet fever, 1.9. The noneffective rate (the number of men per thousand who on the day reported were excused from duty for any injury, sickness, or indisposition whatever) was 31.6. The total of deaths for the week ending November 9 was 8; from disease, 4; 3 from pneumonia, and 1 from heart disease; from wounds received in action, 3; from accidental gunshot, 1.

Civilian Practitioners May Help Prevent Camp Scourges.—Medical officers of the Army and Navy have been somewhat concerned over the frequency with which infectious diseases of all kinds develop among recently drafted men, which stands out in contrast to the remarkable freedom from infectious diseases in the regular army. Following a conference held in Washington last month between various prominent officials and medical officers of the Army and Navy, a call has been issued to the medical profession practicing among the civilian population in the territory in the vicinity of military camps to exercise the greatest caution in preventing the spread of infectious diseases to the men of the camps. A meeting to consider the ways in which the civilian practitioner could best do his bit in this direction was held by the Kings County Medical Society in Brooklyn on November 20. Major William F. Snow was detailed by the Surgeon General's Office to address the meeting. The Queens and Nassau County Medical Societies held a similar joint meeting in Long Island City on November 27. The goal to be reached through the cooperative efforts of the civil practitioners and military authorities is to reduce the amount of infectious disease in all military camps to as low a figure as that of the regular army.

Stricter Physical Examinations for Drafted Men.—At the suggestion of Dr. Robert L. Dickinson, Assistant Chief of the Medical Committee on National Defense, Charles E. Hughes, chairman of the District Board of Appeals of New York, has appointed a committee of five physicians whose duty it is to try to find a way of reducing the number of physically unfit men who are sent to the army cantonments for service in the National Army. The members of this committee are Dr. E. E. Hicks, Dr. George E. Doty, Dr. J. E. Shuttleworth, Dr. H. T. Raden, and Dr. J. S. Waterman. It is authoritatively stated that from 2 to 9 per cent. of the men sent to camps have been rejected after reaching the cantonments. Officials wish, if possible, to reduce this percentage to zero.

Dr. Blake's Hospital to Care for American Soldiers.—The hospital which Dr. Joseph A. Blake of New York established in Paris soon after the war began, and which has been caring for wounded soldiers ever since, has come under the supervision of the American Red Cross, and is hereafter to be known as American Red Cross Military Hospital No. 2. It will care primarily for wounded American Soldiers.

Army Food Inquiry.—The War Department is about to undertake an investigation of food conditions in the army cantonments because of complaints of waste, most of which were made while the camps were in the hands of contractors. Surgeon General William C. Gorgas has been selected as head of the committee to make these investigations in cooperation with the Quartermaster General's Department and the Food Administration The Food Administration has thus far made no attempt to control, either directly or indirectly, the feeding of the army. It is quite generally felt that the country wishes every American soldier to receive every particle of food necessary to his adequate nourishment, yet it is recognized that some waste exists in the camps. This is explained on the ground that the Government furnishes an adequate supply of plain food, and at the same time the civilian population in the neighborhood of camps make many gifts of large quantities of food. It is pointed out that this is a mistake, and that the only gifts needed in the way of food are delicacies.

Bellevue Hospital Unit Mobilizes.—The Bellevue Hospital Unit, New York City, known as Base Hospital No. 1, has mobilized its 300 members at the Twelfth Regiment Armory. The unit includes 300 members, of whom 35 are doctors and 83 nurses.

Lectures in Military Medicine.—Col. Louis A. La Garde, Medical Corps, U. S. A., retired, has again entered the service, and has been ordered to proceed

to New York for the purpose of presenting a course of eight lectures on military medicine and camp sanitation, and additional lectures on military surgery at the University and Bellevue Hospital Medical College.

Dr. Philip Marvel of Atlantic City has been appointed by Provost Marshal Crowder as an officer of the Medical Reserve Corps to assist in organizing the medical advisory boards of New Jersey in connection with the new draft. Dr. Marvel will have the rank of major.

Deaths in the Service.—A despatch to the Navy Department announces the death of Assistant Surgeon Dudley W. Queen, attached to the destroyer Cassin, which was recently damaged by a German torpedo, in Ireland, on November 20. He joined the naval reserves last May. At the same time General Pershing reported that First Lieutenant Orlando Gochnaur, Medical Officers' Reserve Corps, attached to the British forces, was killed in action on November 6. On the same day, First Lieutenant Alexander J. Gillis of the Medical Reserve Corps, attached to the British Army, was slightly wounded.

Flower Hospital Raises Flag.—Flower Hospital recently unfurled a service flag bearing 120 stars, the gift of Major William Tod Helmuth and Mrs. Royal S. Copeland. When the presentation exercises were over 300 medical students in uniform paraded in the neighborhood of the hospital.

To Increase the Supply of Nurses.—The committee on nursing of the General Medical Board of the Council on National Defense has invited the assistance and cooperation of the woman's committee in its efforts to increase the supply of nurses for home and foreign service. A survey of the present nursing facilities of the country, including trained, untrained, and volunteer workers, has been authorized by the Council on National Defense, and will be conducted under the supervision and direction of the American Nurses' Association. To be effective it must have the cooperation of all private agencies and public boards and bureaus. It is proposed that a campaign of public education be carried on through extensive circulation of personal letters, through a magazine campaign, and by means of public addresses before women's clubs, to stimulate the interest of educated young women in nursing as a war service. The main purpose of the committee on nursing is to keep the nursing care of the same quantity and quality as before the war, without interfering with the future supply of nurses through a breaking down of the machinery of nursing education.

Work of the American Red Cross in France.—Major Grayson M. P. Murphy, Red Cross Commissioner for Europe, has submitted a report of the work in military relief now being conducted and organized by the American Red Cross in France. The preamble to the report states that "First of all the American Red Cross stands ready, as a semi-official voluntary body, to put its money, supplies, and organization at the call of the American Army at every point and at any time, wherever and whenever they can be of use." It organizes and turns over to the Government absolutely the hospital units that are employed in France. The mere titles of the various activities described in this report give some idea of the exceedingly broad scope of the work being carried on. Among the various branches of the work described are the following: Caring for the wounded, rest stations, guarding the soldiers' surroundings by making the region in which American troops are quartered a healthier place, portable kitchens, laundries, baths, ice plants, dental ambulances, ophthalmological ambulances, portable sterilizing plants, portable lighting plants, artificial limb shops, medical and surgical research work, including a study of "shell shock," emergency medical stores, non-medical work, canteens, libraries, help in getting reports of sick, wounded, or missing. The distributing service of the American Red Cross has now 3,617 hospitals on its lists, situated all over France, but most numerous in the departments back of the front. Hitherto a hospital was given one-half the supplies it asked for; now it is given perhaps three-fourths, the French to supply the remainder. It is prepared to furnish expensive equipments, such as radiographic installments, sterilizing plants, and special instruments needed by surgeons. The Red Cross in France is being reorganized, and is attempting to build up reserves that will enable it to meet any emergency of any size that may present itself. Although they have been adding to the number of hospitals at the rate of 100 a month, there are not at present hospital accommodations sufficient to care for the rapidly growing personnel of the American civilian workers in case of an epidemic. Thus far, arrangements have been made for 30 beds at the American Hospital at Neuilly for the care of Red Cross workers.

Model Section Hospital.—A model of a "Liberty" field hospital, built in sections, and suitable for use in the army, and in Red Cross and general hospital work. has been designed by Dr. Henry Fairfield Osborn, president of the American Museum of Natural History, in cooperation with H. F. Beers, superintendent of construction of the Museum. A large model is on exhibit at the American Museum of Natural History, New York. The hospital is ingeniously constructed in five-foot units, so that it can be taken apart and reconstructed by unskilled labor, and so that space can be saved in transporting it. The average hospital of this kind is from 150 to 160 feet in length and 24 feet wide.

More Bombing of Hospitals.—The Belgian minister has sent to the Department of State in Washington a protest against the Teuton practice of singling out hospitals for bomb targets. He writes that "On the evening of September 26, 27, 1917, German aeroplanes wilfully bombarded the Belgian sanitary formations at Calais and Petit Fort Philippe, and, notably, dropped three bombs on the military hospital at the Gravelines gateway, causing several casualties. The Red Cross emblems were conspicuously displayed on those establishments." The minister, in the name of his government, "denounces this new and flagrant violation of international law to the international committee of the Red Cross and to the allied and neutral governments which have signed the Geneva international convention of July 6, 1906."

MEDICAL RECORD.

THE EDEMA OF CHRONIC PARENCHYMATOUS NEPHRITIS.

THE causation of edema has long been a fertile topic for speculation by pathologists as well as clinicians, and while the explanation of certain forms of edema, the mechanical for example, seems comparatively easy, the mode of production of certain other forms, that associated with kidney disease, for instance, has never been satisfactorily elucidated. Among the theories advanced to account for this we find alteration in the secretory power of the endothelium of the blood vessels, pathological changes causing increased permeability in the vessel walls, retention of water in consequence of lessened permeability of the renal blood vessels, retention of salts in consequence of the inability of the kidneys to excrete them, altered composition of the blood, and acidity of the body colloids causing them to absorb and retain water. Although the toxic theory is supported by the results of experiments with uranium nephritis and by the fact that the injection of the blood serum from edematous nephritics into animals will cause an increased production of lymph and also that the fetus is usually edematous in the nephritis of pregnancy, nevertheless the most generally accepted hypothesis is probably that there is an inability of the kidney cells to eliminate sodium chloride, the accumulation of the latter in the body naturally causing a retention of water and consequent edema.

All these theories are rejected by Albert A. Epstein (*American Journal of Medical Sciences*, November, 1917), who holds that the edema in chronic parenchymatous nephritis is a direct result of the loss of albumin. The tissue fluids and the plasma in health are of practically identical composition except that the plasma contains more protein than the tissue fluids. The result of this is that the osmotic pressure of the blood is greater than that of the tissue fluids and so the direction of flow is from the tissues into the capillaries. In parenchymatous nephritis, however, this balance is disturbed by the lessened colloid content of the blood resulting from the albuminuria; the osmotic pressure of the blood is reduced with the result of imbibition and retention of fluid by the tissues.

The practical therapeutic application of this theory is rather startling. If there is any consensus of medical opinion regarding the dietary management of chronic parenchymatous nephritis, it is that the intake of protein and of animal protein in particular, except that of milk, must be restricted in order to reduce the amount of waste products and so prevent their accumulation and poisonous action in the body, and likewise to lessen the work of the kidneys. Epstein, however, with the courage of his convictions, advises the administration of protein in large amounts, up to 120 to 240 grams daily, in order to compensate for the loss in the blood content caused by the sustained albuminuria. The protein in the diet which he prescribes is derived not only from peas, beans, and other albuminous vegetables but also from veal, ham, eggs, and oysters. If this theory of the production of edema in chronic parenchymatous nephritis is correct, this excessive protein intake ought naturally to reduce the anasarca, but the latter is only one symptom of the disease and it is difficult to understand how the local pathological changes, which preceded the dropsy, can be cured or even appreciably benefited by reducing the latter at the cost of increasing the albuminuria and so adding to the burden of the damaged kidneys. However, Dr. Epstein says that the results obtained in the small number of cases treated after this plan have been very encouraging, and he promises a detailed report of these cases in a later publication.

ARGYRIA.

OF the two forms of argyria, industrial and medicamentous, the latter has become very rare, save for certain local manifestations due to topical applications. It is, however, well known that the year long use of the silver stick in the mouth and pharynx can produce universal argyria. Industrial argyria, including the universal form, was exhaustively considered by Koelsch in 1912. The internal medicamentous use of silver salts is almost a thing of the past, but this is largely offset by the increasing local use of numerous organic silver preparations and of colloidal silver. Hence, basing his work on that of Koelsch, with personal cases of medicamentous argyria, Steiger has written exhaustively of the general condition in the *Correspondenz-Blatt für Schweizer Aerzte* for September 15. In regard to its pathology, argyrism resembles in certain respects other impregnations with salts of heavy metals. The gums are the site of the initial deposits of the minute particles of silver, and a silver line, grayish violet, is formed, which is quite analogous to the lead line. The deposits in the skin show a striking affinity for the elastic fibers, while the collagenous tissues are practically spared. Of the internal organs only the brain and cord show immunity, but as a rule the organ pulp is spared and the deposits occur in the interstitial supporting tissue, in which elastic fibers are present. These minute foreign particles seem to cause no irrita-

tion and it is supposed that the silver unites with the tissues with formation of an organic compound (albuminate). The weight of evidence goes to show that no silver is excreted by the kidneys. It never enters the epidermis or hair and so cannot be eliminated in this manner.

Despite its inert behavior argyria is attended by certain symptoms, of which the subjective ones are perhaps due in part to suggestion. A sort of withdrawal syndrome is said at times to follow prolonged cessation of the exposure to the drug. This subsides when the applications are renewed. Argyria may be in evidence within 6 months after steady brush applications to the tongue of solution of nitrate, corresponding to two months' internal exhibition, but there are plenty of cases in which strong solutions have been used for a much longer period (several years) before the appearance of the discoloration. In the industrial type over 20 years may elapse before the appearance of the peculiar discoloration (glass pearl workers).

Since the silver deposit in the skin is practically a tattooing with an insoluble, unabsorbable substance, argyria is beyond our therapeutic resources. The only chemicals which in theory could dispose of the silver particles are strongly toxic. In a solitary case the use of hexamethylenamin was followed by the clearing up of a dark blue deposit. The author reports four personal cases. In the first one the nitrate had been given in pill form to a middle-aged woman with multiple sclerosis. In 7 months she took nearly 4 gm. of actual silver and developed total argyria. The uncovered areas of the body were silver gray with metallic luster, while the protected localities were pale gray. Silver was found in the stools. At the time of menstruation the skin looked darker. The second patient was a middle-aged woman with gastric ulcer. During a period of 13 years she ingested 2.6 gm. of silver as nitrate. Argyria did not appear until 10 years after treatment began. The condition was universal. A slight paling of the skin after cessation of treatment was computed to emigration of some of the granules to the proper lymph nodes. The third patient, a man of 56, received the nitrate for tabes dorsalis for a period of 5 years. Argyria began after 4 years and became universal. The fourth case was one of local argyrosis of the conjunctiva. The patient had received over a hundred brush applications of nitrate solution for trachoma.

A word as to industrial argyria. Bohemian glass workers in silvering glass pearls suck into the mouth a solution of silver nitrate, ammonia, and potash lye, and constantly, although unintentionally, swallow a little of it. The conditions therefore parallel those of medicamentous exposure. Again, girls who work in silver inhale a dust slightly impregnated with the metal. Koelsch saw 2 cases of total argyria of this origin. The subjects bore out the ancient dictum of Hebra that anemic blonds are predisposed to this accident. Finally, total argyria has followed injections of colloidal silver into the bladder, although this accident very rarely follows injection of this solution directly into the blood.

AN UNJUST DISCRIMINATION AGAINST PROFESSIONAL MEN.

In the war revenue bill passed just before the adjournment of Congress a couple of months ago, is a section which will bear very heavily on all medical men having an income from their profession in excess of $6,000. After providing in section 201, for graded taxation upon excess profits, above those of the pre-war period, earned by partnerships or individuals, after the deduction of an amount calculated upon the basis of a percentage of the invested capital and of $6,000, the bill contains a section which reads as follows: "In case of a trade or business having no invested capital or not more than a nominal capital, there shall be levied, assessed, collected, and paid in addition to the taxes under existing law and under this Act, in lieu of the tax imposed by Section 201, a tax equivalent to 8 per cent. of the net income of such trade or business in excess of the following deductions: In the case of a domestic corporation, $3,000; and in the case of a domestic partnership or a citizen or resident of the United States, $6,000. In the case of all other trades or business, no deduction."

In a previous section it is stated that "the terms 'trade' and 'business' include professions and occupations." The consequence of this is that any medical man whose income, derived from his practice, exceeds $6,000 per annum will have to pay a tax of 8 per cent. of the excess, in addition to the income taxes payable under other sections, without regard to whether such income is in excess of the pre-war income. If this tax were levied on all incomes in excess of $6,000, no matter whence they were derived, there would be no complaint registered by members of our profession. But the bill in effect discriminates against the professional man in favor of the inheritor of wealth. For instance, a man whose father or grandfather left him an estate which brings him in $10,000 a year without any labor on his part beyond that of clipping coupons, which he has his secretary or a clerk do for him, pays $320 less tax than the physician with a laborious practice bringing in an income of the same amount. Thus the law puts a penalty on industry, and it bears with special weight on the medical profession which is already doing more than its share, and doing it gladly and without complaint, in the war. There is no other profession or trade that has given such a large proportion of its members to the cause. Already 15 per cent. of the physicians of the country, irrespective of age, are in the service, and if the army is increased to 5,000,000 men, as it will be if the war continues two years longer, at least 25 per cent. will be taken. If, in addition to this, 10 per cent. or 50 per cent. of the income of those too

old or otherwise unfit for service is taken in taxes there will be no complaint, provided it is taken in equal measure from all. But there should be a strong protest against the injustice of this bill which spares the drone and penalizes the hard-worked professional man.

An effort will be made during the coming session of Congress to repeal this section of the income tax bill, and there is reason to hope that the effort will succeed. To make the repeal certain every physician should, whether his income has yet passed the limit of exemption or not, write to his representative in the lower house and to the senator from his State, setting forth the unfairness of the tax and urging a repeal of the obnoxious section.

PROFESSIONAL APOPLEXY.

DESPITE the fact that medical men look upon apoplexy as nine-tenths predisposition, the courts and laity have at times regarded it as almost traumatic in its nature. The physician thinks in terms of the blood pressure, hypertrophy of the heart, and vascular degeneration, and to a much less extent of muscular effort and emotional stress, for these factors only precipitate an inevitable accident. An exciting cause may be minimal, as sudden exposure to cold, or absent altogether. The following case, however, seems unique throughout.

In *Il Policlinico* for September 23 is an account of a judicial decision which awarded to the widow a pension in the satisfaction of a claim against the State of a magistrate who died in a few hours of apoplexy while engaged in his regular occupation. It was the first instance of its kind in the history of that tribunal, and the judgment was rendered with the approval of the sanitary chief of the jurisdiction. The victim was but 43 years of age. Two physicians, called in haste, made the diagnosis by lumbar puncture. In the opinion of the judge the victim was too young to have senile vascular degeneration. Precocious arteriosclerosis, except as stated later, was improbable, because there was no evidence adduced which pointed to such a factor (absence of gout, no history of typhoid). The "apoplectic habit" was not in evidence, but the very reverse. Syphilis, malaria, nephritis, were all excluded, as were alcoholism, plumbism, and other intoxications. There was no apoplexy in the family.

The victim's occupation was the only factor judged able to produce such a condition of the blood vessels as to make rupture inevitable. He had been an indefatigable worker for many years, with very long hours, and while other forms of arteriosclerosis could be presumably excluded, it was held that the accident could not have occurred in the absence of this condition, which was termed "professsional arteriosclerosis" in correspondence with "professional apoplexy." The man had been a slave to duty, as he understood it. The fact that many other professional men work as hard with impunity had no practical bearing on this case. Contributory neglect does not seem to have entered into the merits of the case. The operation of an exciting cause, which elevated temporarily the blood pressure, was assumed to have been present, but so many factors could have been active here that there was no attempt to isolate a particular one. In any case, the direct, immediate cause of death was a condition of the cerebral blood vessels, due to intense and sustained mental activity. The exciting factor, if any, could only have existed in an attempt to finish the task of the hour within a specified time, and this devotion to duty was characteristic of the man.

News of the Week.

Workmen's Compensation Laws.—At the annual meeting of representatives of insurance companies composing the Workmen's Compensation Publicity Bureau, held in New York City, on November 23, the report of the secretary on the year's legislative record showed that only eleven States were without any kind of workmen's compensation laws. Of these all were in the South except North Dakota. The legislative policy of the bureau is "not merely to assume the hands-off attitude towards proposed reasonable and practicable workmen's compensation legislation, but to be of every possible assistance to all organizations in formulating, initiating, promoting, and effecting such legislation."

The Fatal Grade Crossing.—A report by the Committee on Grade Crossings of the National Association of Railway Commissioners states that of 10,785 trespass accidents in 1914, 3,437 happened to men between the ages of 21 and 30—in other words, the country lost over 3,000 men of draft age. There are, according to this report, 200,000 grade crossings in the United States and on an average 2,000 persons are killed each year at these crossings. In the work of eliminating grade crossings Illinois stands at the head with an expenditure of fifty-five million dollars. In the opinion of the committee, the more attention paid to the dangers of grade crossings the better it will be for all who journey upon the highways.

Fire in Hospital.—A fire in the Blake Memorial, a maternity ward of the General Hospital at Elizabeth, N. J., early on the morning of November 18 caused damage estimated at $2,000.

Red Cross Christmas Seals.—The State Charities Aid Association announces that Christmas seals for the tuberculosis fund are on sale throughout the State of New York. It is expected that the State, outside the city of New York, will buy $150,000 worth of these seals.

Insane Women Doing War Work.—About 100 patients in the State Hospital for the Insane at Middletown, Conn., whom heretofore it has been difficult to keep employed, are said to be contentedly engaged in knitting and making bandages.

Free Dental Clinic.—The New York College of Dentistry has opened a free clinic Saturday afternoons from one to four o'clock. The teeth of poor children between the ages of seven and fourteen years will be cared for entirely without charge.

Street Accidents.—According to the report published by Police Commissioner Woods, there were 2,389 persons killed or injured in street acci-

dents during the month of October. Of these 777 were children and 383 more than 50 years of age. The total casualties are smaller than those for September, which were 2,503. Automobiles killed 19 persons on the streets and injured 755; motor trucks killed 11 and injured 267.

Fewer Drink Cases in the Courts.—A report recently submitted by the chief statistician of the City of New York shows that there has been a reduction in the number of intoxicated persons dealt with in the magistrates' courts of the city for the first nine months of the present year. During this period there were 4,508 intoxicated persons dealt with, as against 5,050 during the corresponding period of 1916.

Resolution Before the County Medical Society.—The following preamble and resolution were offered by Dr. John P. Davin at the meeting of the Medical Society of the County of New York, held November 26, and were referred to a special meeting, to be called at an early date, for discussion:

Whereas, The Medical Society of the County of New York has for the past 120 years been deeply interested in and devoted much labor to the public health conditions of New York City; and

Whereas, The aims of this organization are the same as the New York City Board of Health, namely, the betterment of health conditions in New York; and

Whereas, The Board of Health and the medical profession, as represented by the Medical Society of the County of New York, must cooperate if the best results are to be obtained; and

Whereas, For several years the medical profession has had to contend against measures and methods which were inimical to the welfare of those connected directly or indirectly with the private practice of medicine, and such measures and methods were promulgated without the knowledge of the organized medical societies; and

Whereas, This condition should now be obviated by the Medical Society of the County of New York by offering to the incoming municipal authorities its point of view on these conditions, and assuring such authorities of our desire to cooperate with them in every way, in order to avoid a continuation of this condition; therefore, be it

Resolved, That there be appointed from the body of the Medical Society of the County of New York, a regularly organized medical body of this city, a committee to carry out the spirit of this resolution, as a matter of duty on the part of this society to its members in defense of their rights as lawful practitioners of medicine.

Sanitary Squad Out After Spitters.—In order to make more effective certain of the sanitary ordinances the Health Department of New York City makes it a practice to occasionally concentrate attention on certain ordinances. This being the season when the prevalence of respiratory diseases usually increases and when these diseases are most likely to be spread through the carelessness of infected individuals in disposing of their sputum, a campaign is being actively prosecuted against those who spit in public places. Commissioner Emerson has written to the police magistrate requesting him to "act with determination in imposing suitable sentences on all such offenders." Last year 1,500 persons were arrested for violating this ordinance and in many instances a fine of $5 was imposed. On the first day of the campaign 88 spitters were fined $2 each and 206 were given suspended sentences. Violators of the ordinance will be served with summonses to appear in court instead of being arrested.

The Control of Venereal Diseases in Rochester.—The health officer of Rochester, Dr. George W. Goler, has devised a unique method of keeping venereal disease patients under dispensary treatment. The plan calls for regular periodic visits to the department's clinic by each patient. He is told upon leaving when he is expected to come back again, and if he does not appear a written notice is sent to his house, stating that unless he presents himself immediately for further advice and treatment he will be visited by a police officer. If he still persists in neglecting treatment a warrant for his arrest is sworn out and he is haled into the local police court and committed to the care of the health department for an indefinite period.

Dr. Katherine B. Davis, who was recently appointed head of the New York Parole Board, has resigned the position to accept the secretaryship of the Rockefeller Bureau of Social Hygiene.

Dr. Theron J. Vosburgh has been appointed superintendent of the city farm at Warwick, N. Y., which is conducted by the New York City Board of Inebriety, to succeed Dr. Charles S. Stokes, who resigned a few months ago. The position pays a salary of $5,000.

Charitable Gifts and Bequests.—The Home of Our Merciful Savior for Crippled Children in Philadelphia is the recipient of $5,000 and one-half the income from a trust fund, bequeathed by the will of the late Sarah M. Gardner of Providence, R. I.

The Germantown Hospital and Dispensary of Philadelphia has received a bequest of $100,000 by the will of the late Mary Warden of Herkness, N. Y.

A benefit for the babies' ward of the Post-Graduate Hospital, New York, has netted that institution $1,000.

Positions in Health Service of Alabama.—The Health Board of Alabama calls attention to three vacancies which pay $150 a month, with additional expense money for rural sanitary work. These salaries will be increased to $175, with expense money, on January 1. There are also two places open for full time health officers, one of which pays $3,000 and the other $2,500.

The Southern Gastro-enterological Association, which met in Memphis, on November 12, reelected the following officers: *President*, Dr. J. G. Johnson of Atlanta, Ga.; *Vice-President*, Dr. J. T. Rogers of Savannah, Ga.; *Secretary-Treasurer*, Dr. M. H. Smith of Jacksonville, Fla.

The Late Dr. Richard Weil.—The following minute has been adopted by the board of trustees of the Memorial Hospital: Dr. Richard Weil, Major in the Medical Reserve Corps, U. S. A., died while on active duty at Camp Wheeler, Macon, Ga., November 19, 1917. By his death the Memorial Hospital loses one of the most highly trained and successful workers of its medical staff, and American cancer research one of its recognized leaders. Since

1906 Dr. Weil has been an active member of the staff of the Huntington Fund, and throughout this period of eleven years he was constantly engaged in the problems of cancer research. His contributions in the field of the serology of cancer and in the general problems of immunity gained for him an international reputation. He was one of the founders of the American Association for Cancer Research, and largely through his efforts was founded the *Journal of Cancer Research*, of which he was editor-in-chief. At the reorganization of the Memorial Hospital in 1913, Dr. Weil assumed the position of assistant director of cancer research and attending physician to the hospital, and in this capacity he labored energetically to establish an efficient organization of the routine and research work of the hospital. In 1915 he resigned the position of assistant director upon his appointment as professor of experimental medicine in Cornell University, but he continued without interruption his experimental work in cancer. Upon the declaration of war he was among the first to offer his services to the Government, and spent the summer at Fort Benjamin Harrison in the Medical Officers' Training Corps. Quite recently he was detailed to take charge of a large military hospital at Camp Wheeler, Macon, Ga., and here in the performance of strenuous military service he fell a victim to pneumonia. During his brief but brilliant career he attained eminence as a devoted laboratory worker, a skillful experimenter, a broadly trained clinician, and a forceful writer, while his untimely death places his name among the first on his country's honor roll in the great war.

Obituary Notes.—Dr. ARCHIBALD G. THOMSON of Philadelphia died, on October 22, at the age of 46 years. He was a graduate of the medical department of the University of Pennsylvania, in 1892, a member of the American Ophthalmological Society and the Medical Society of the State of Pennsylvania and a Fellow of the College of Physicians of Philadelphia.

Dr. HONORE J. COTE, a graduate of the Boston University School of Medicine, in 1899, died at his home in Boston, on November 10.

Dr. JOHN Z. CURRIE of Cambridge, Mass., a graduate of Harvard University, in 1873, died suddenly on November 10, aged 70 years.

Dr. PAUL S. MORRISON of Bancroft, Kan., a graduate of Ensworth Medical College, St. Joseph, Mo., in 1909, died in an Atchison hospital from injuries received in an automobile accident, on November 2, aged 34 years.

Dr. GEORGE LINDENMEYR, a graduate of the College of Physicians and Surgeons, New York, in 1888, died at his home in New York City, on November 15, aged 51 years.

Dr. MARY J. GREEN, a graduate of the Woman's Medical College of Pennsylvania, in 1878, died at her home in Philadelphia, on November 4, aged 76 years.

Dr. JOSEPH M. GERHART, a graduate of the Homeopathic Medical College of Pennsylvania, in 1868, died of pneumonia at his home in Philadelphia, on November 19, aged 75 years.

LIEUTENANT G. WALTER H. CONRAD of the Medical Reserve Corps of the United States Army, a resident of Philadelphia, died at San Antonio, Tex., on October 29, aged 29 years.

Obituary.

AMI JACQUES MAGNIN, M.D.

PARIS, FRANCE.

DR. AMI JACQUES MAGNIN, formerly of New York City, died suddenly in Paris, November 26. Born in 1858, he was graduated from the Bellevue Hospital Medical College in 1881. He was interne in Bellevue Hospital in 1882.

Having practised in New York for several years, Dr. Magnin accepted the position of assistant to the medical director in Paris of the Equitable Life Insurance Company. Possessed of a high order of professional and social talent, he soon acquired an acquaintance of unusual extent and value. His versatility as a practitioner was remarkable, his knowledge of clinotology in particular being extensive and accurate.

More than ten years ago the need of a special hospital in Paris for the care of visitors from the United States suggested itself to Dr. Magnin. He at once secured the cooperation of several influential friends and organized the American Hospital. This institution, with the aid of well-chosen associates, he developed into the best model of its kind in Europe.

At the outbreak of the present war he selected the building now occupied by the American Ambulance and aided in the organizing of a surgical staff for the new institution from the staff of the already existing American Hospital. Always unsparing of himself, the added burdens of the war have overwhelmed him. D. B. D.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL EXAMINATIONS—VICTIMS OF AIR RAIDS.

LONDON, November 2, 1917.

SIR RYLAND ADKINS told the Select Committee on medical reexaminations his experience as a member of an appeal tribunal and chairman of a county recruiting committee. He felt in an increasing degree that the arrangements for examination, and more particularly for reexamination, were not working in a way to give the tribunals all the assistance they would like. "We are faced," he remarked, "with remarkable contrasts in the classifications of persons who come before the tribunals. When we have men who have been rejected in 1915, and again last year, coming before us, passed A or B1, with an unvarying record from private doctors, it is very difficult to know where our duty lies." Sir Ryland said that his experience was that the difficulty of getting medical decisions thoroughly satisfactory to act upon had become greater since the act authorizing reexaminations. The impression produced on him, said Sir Ryland, regarding complaints as to tearing up certificates, was that while he would be the last to ask the committee to believe every story of the kind, one could not sit week after week and listen to these stories without coming to the conclusion that there was some ground for them. One remedy for the existing state of things was that certain doctors, of at least 50 years of age, should give up one or two days a week to

sit upon the board, two-thirds of which should be composed of experienced local practitioners of recognized character and prominent in their profession. Sir Ryland further referred to some instances of the raising of men from low to high degrees with almost inexplicable quickness, and declared that this want of security produced a bad effect on public opinion. The fact that presidents of boards were in a position to overrule the decision of the other members affected public opinion to the prejudice of the army. In reply to a question, he said there had been complaints about examinations being too rapid and too cursory, and on one case being further inquired into it was found that it was not so perfunctory as had been represented. He admitted that, logically, men who had been taken into the army with lowered category should have the right for their cases to be reconsidered by the tribunals. Out of 38 men who had been passed for general service and sent by the tribunal to the Special Medical Board 7 were rejected, and the remainder placed in a lower category.

Mr. Crooks attested to the splendid behavior of the people of East London during the last air raid, and said the Germans had found out that they could neither starve nor make cowards of us. At the inquest on 46 victims of the explosion at Ashton under Tyne, Mr. Slater, chemist at the works, said he was there on June 13, about 4 o'clock, with Mr. Dreyfus, who was killed. He saw flames coming out of windows of the works where chemicals were boiling in a pan, and ran up the steps to the room to let the heat out. He did everything he could until he was overcome by the fumes. The packing room was on fire and full of fumes. Mr. F. Slater said he was blown across the street in the midst of fumes and flames, and remembered no more. Jas. Jones said that while working at the gas holders, next to the munition works, he heard an explosion, and saw smoke and flames coming from the works. He heard another terrible report, and hot pieces of metal were blown with great force against the gas holders and made holes in them. The liberated gas caught fire and enveloped the holders in flame and smoke, but the holders did not explode. The whole of the chemical works was in a blaze. The flames passed him, and he was slightly burned. He lay on the ground stunned for some time and then dropped over a wall into the street. The coroner referred to the heroism of the workmen and others in trying to subdue the flames before the explosion, well knowing they were imperiling their lives for their country just as much as soldiers on the field.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

WAR ORPHANS—NEW SCHOOL FOR THE BLIND—RECEPTION TO AMERICAN NURSES—THE FIELD AMBULANCE SERVICE.

PARIS, October 16, 1917.

EVER since the organization of the American National Committee for the raising of a vast sum of money to be expended for the war orphans of France, the various societies of that country have been eagerly inquiring where, how and when they could secure some part of the money to aid their work.

A committee composed of Americans was appointed in Paris to work in conjunction with the American coimmittee, and the members of this committee have had their hands full in listening to and investigating the claims of a great number of societies organized for the relief and care of these most unfortunate of all unfortunates of the war.

The work of this committee has just been taken over by the Red Cross, in pursuit of the highly important purpose of centralizing the relief work of all American societies in France under one national organization. From an administrative point of view as well as for the systematic collection of funds, it is highly important to centralize war relief appeals and executive methods of distribution under one national organization. In fact, the Government has demanded that all relief organizations be coordinated under Red Cross control. Turning over to the Red Cross the responsibility of caring for the existing lists of orphans and of the thousands of others who will be deserving of future solicitude and help, it is believed they will profit by the specialized and scientific knowledge of the distinguished men who are devoting themselves to the Red Cross service.

Following this general plan of absorption and centralization, a new school for the superior reeducation of the blind was turned over to the board of directors on Monday by M. Eugène Brieux of the Académie Française and president of the French section of the fund, and the school will be formally opened for the blind next Monday. It is located at 27 boulevard Victor Hugo, Neuilly, in a spacious building with extensive gardens which was formerly a seminary for young ladies. The premises have been leased and thoroughly equipped for a school for the blind by Mrs. Kessler, and given over in the name of the Permanent Blind War Relief Fund to the French section. It will add another chapter to the already extensive work of this unusual war relief fund, which not only promises aid to the blind for the duration of the war, but permanent aid to the victims during their entire lives.

This fund has already guaranteed a pension of 1,200 francs a year for life to every soldier both blinded and seriously maimed, in addition to purchasing cottages for many of them. It has opened extensive workshops where a full stock of raw materials is kept and supplied, at cost price, on credit, to every reeducated blind man. It has a knitting and weaving school at 35 boulevard du Château, Neuilly, Paris. It sends every blinded man who has no private means, after his reeducation in no matter which school, to his country town or village, paying his rent for one year and furnishing him with the means of reestablishing himself and earning his own living.

The American Group of the Lyceum Club of Paris placed its Salle des Fêtes at the service of the delegation of twenty-two head nurses from America, who met in conference yesterday afternoon for the consideration of their future work. Miss Martha Russell, formerly superintendent of the Sloane Hospital in New York, and now head-nurse serving under the American Red Cross in France, presided.

At the close of the conference Miss Russell and her coworkers were received at tea by the Group.

Mrs. Sharp, who has recently accepted the honorary presidency of the Group, was present. The acting president, Mrs. Arthur Valois, assisted by Duchesse d'Uzès and the women of the special committee, received the guests.

The Group has been approached with the suggestion that it should concern itself with the American nurses, of whom there are already one thousand serving under the Red Cross in France, and has been asked to consider the matter of taking an active part in giving welcome to nurses during their period of rest and recreation which they will pass in Paris.

The American recruiting officers for the United States Army Ambulance Service, which is absorbing the American Field Service and the Harjes-Norton Red Cross Service, have recently returned to Paris after visiting the scattered sections of the two services along the French front for the purpose of enlisting the men in the army. They report the percentage of enlistment is but little over fifty instead of eighty, as was indicated by the first two or three sections which were enlisted in the Field Service. The large number of American boys who are now observed on the streets of Paris wearing the uniform of the American Field Service and the Harjes-Norton Service are principally those who have not enlisted in the United States Army and have been released from the two services. They will either enter other services of the army or return to the United States to try their hands at getting commissions.

3. Lymphocytosis: A Clinical Study from Group Diagnosis.—J. Marion Read states that the lack of consideration which a lymphocytosis receives at times is, in part, accounted for by the great number of pathological states in which it is present. On account of this the field of differential diagnosis is considerably widened if one tries to fit this blood-finding into the clinical picture. Ofttimes it is a part of some minor, concomitant disease, and thus its existence is accounted for. He made a study of lymphocytosis from the viewpoint of grouping the pathological conditions, because this type of clinical investigation unearths every pathological condition that a patient may harbor. Every abnormal sign finds its place, or the investigation is continued until the clinical picture is clear. He groups the pathological conditions characterized by an increase in the lymphocytic elements in the blood into two groups, according to the mechanism of their production. One form is a true lymphocytosis marked by hyperemia of the lymphatic structures of the body, with an actual increase in the total number of large and small lymphocytes. The second form is a pseudolymphocytosis, and is produced by a mechanical forcing of the preformed cells into the general circulation from their recesses in the spleen and other lymphatic structures. This is not marked by an actual increase in the total number of mononuclears in the body and is only transient in the greater number of cases. Mention is made of the experimental lymphocytosis produced by the injection of certain substances such as adrenalin, muscarine, pilocarpine and barium chloride. Harvey showed that this was purely mechanical and produced by contraction of the arterioles of the spleen, which was actually reduced in size. This comes in the second group. He gives four physiological states marked by a mononucleosis: (1) In infancy and childhood, the spleen, thymus, tonsils and lymphatic structures in general are large and active, with a consequent increase in the lymphocytes even to half of the white cells. Children respond quickly with a rather high lymphocytosis to many infections and abnormal conditions, which in adults are accompanied by little or no change in the blood picture. It is quite likely that to this fact can be attributed many of the lymphocytes which have been observed to occur in measles, scarlet fever, mumps, anterior poliomyelitis, ringworm, and other diseases more prevalent in childhood. (2) Attitude has been shown to be a cause of lymphocytosis by Bar and Engelmann in Germany, and Stains, James, and Rosenberg in this country. The mechanism of this increase is most likely that of the second group. (3) The ingestion of fat and carbohydrates seems to call forth lymphocytes. Rous has shown an increased output of mononuclears from the thoracic duct after the administration of glucose, and maintains that the number of hyaline cells in the blood is materially increased through this mechanism. But, as another possible explanation, we have Bergel's demonstration of the chemotaxis which exist between lymphocytes and lipoid substances in the blood. (4) A sudden mononucleosis occurs after exercise, the absolute number even being doubled in some cases. This mechanism is, of course, that of the second group. The numerous pathologic states characterized by an increase of the hyaline cells can, for the purpose of study, be grouped with considerable advantage. As a result of his investigations he states that, remembering the chronic mouth infections discussed in his paper, he is inclined to think that these, other than tuberculosis and syphilis, may be accompanied by a mononuclear increase. The most typical example of lymphocytosis and leukopenia among the infectious diseases is typhoid fever, in which, during the third to sixth week, the hyaline exceed the granular casts. This so called "crossing of the leukocytes" is regarded as having considerable prognostic value, for in unfavorable cases it does not occur. Glinchikoff found an increase in lymphocytes during vaccination against typhoid. Read's conclusions are: (1) The lymphocytosis occurring in tuberculosis is more apt to be a relative than an absolute one and is more marked in healed cases. (2) A lymphocytosis in syphilis is less frequent than in tuberculosis, but an absolute lymphocytosis, especially when accompanied also by eosinophilia, is suggestive of luetic infection. Those cases of syphilis which show a lymphocytic increase are most apt to have a positive Wassermann reaction. (3) An absolute increase in lymphocytes is often accompanied by an eosinophilia. (4) Chronic mouth infections, especially when associated with diseased or hypertrophied tonsils, cause an increase in the mononuclear elements of the blood.

3. A New Conception of Arteriosclerosis.—Ignatz L. Nascher considers that the conflicting views of arteriosclerosis are so at variance that it is impossible to

harmonize them. He offers another conception of this condition, which he believes is clear and true to the literal meaning of the term, and gives a distinct impression of a definite reality. Arteriosclerosis is literally a hardening of the arteries, but the term is too often used to imply conditions which have but this one feature in common. He thinks that the term should be restricted to its literal significance. It may be a fibrosis, a calcification, a muscular hypertrophy, or an inflammatory thickening. It may be a relative hardening while in a state of contraction or an actual hardening without histological change. It may be physiological or pathological, primary or secondary, temporary or permanent, local or general. The essential feature in every case is a hardening of the arterial wall, whether local, as compared with the walls of arteries elsewhere, or general, as compared with the healthy arteries of a person of the same age. As arteries harden normally from birth to old age and harden more rapidly in advanced life, it is impossible to fix a standard of hardness. The term hardness is here purely relative. The term arteriosclerosis is applied to a number of pathological arterial degenerations as well as to the normal physiological degeneration occurring in old age, and as the only test of hardness aside from the tactile sense is the blood pressure which is dependent upon a number of other factors than the hardness of the vessel, the term is frequently applied to conditions in which the arteries are normal. Indeed, the term is often applied to any condition presenting high blood pressure without albuminuria. He finds eight distinct forms of arteriosclerosis. In three forms, the pure sclerotic, the vasomotor, and the hypertrophic, there are no histological changes, but these forms may become degenerative. There are probably several varieties of the irritative or inflammatory form, depending upon the character of the irritant. The gummatous formation occurring in syphilis does not occur in any other form of arterial degeneration. Other pathological degenerations may give other distinctive characteristics by which they may be distinguished. The mechanical form always begins in the media, while in the perverted nutritional form the whole vessel is involved. The nutritional form begins in the vasa vasorum, where an endarteritis can be demonstrated long before the endothelium of the main vessel is affected. In the perverted nutritional form there is no vasa vasorum endarteritis. The embolic form presents the characteristics of the irritative form and the nutritional changes of the nutritional form without the histological changes in the nutrient vessels. General causes, as ageing, adrenal hyperactivity, thyroid inactivity, and constitutional disease in which soluble toxins are elaborated, affect the entire vascular system. Local factors will influence the site, rapidity, and extent of local degenerations even where there are general causes. In parts doing excessive work the vessels degenerate early, and hence we find usually earlier and more pronounced arteriosclerosis in the right arm than in the left. The aorta receiving the entire amount of blood from the heart and being subjected to the greatest strain is most frequently and most extensively involved. Brain workers present symptoms of cerebral arteriosclerosis much more frequently than manual laborers, although the latter show more marked mental impairment in old age. It is rarely possible to determine clinically the form of arteriosclerosis. In many cases the etiology gives the clue, occasionally the result of treatment clears up the diagnosis. He points out a factor which is usually not considered among the factors concerned in blood pressure. All authorities declare that blood pressure depends upon heart action, arterial tension, and peripheral resistance. None takes into account the viscosity or density of the blood itself. Yet it is known that under the same pressure a dense or viscid fluid will flow through a tube, whether rigid or resilient, more slowly than a thin fluid, as the thick fluid offers greater frictional resistance to the walls of the tube and is itself more resistant to pressure. In some conditions, as anemia, tuberculosis, and underfeeding, the blood is thin and of low specific gravity, and the blood pressure is low. In nephritis and other diseases in which the specific gravity of the blood is high the blood pressure is high. Blood of high specific gravity passes through the arterioles and capillaries with greater difficulty, increasing the peripheral resistance, and adding another factor to its own density to raise the blood pressure. In the aged the specific gravity of the blood is from 1050 to 1060; there is a physiological mechanical arteriosclerosis, increased activity of the heart to overcome the lessened tonicity of the vessels, and increased peripheral resistance. Thus all factors raising blood pressure, including greater density of the blood, combine to raise the blood pressure in the aged.

7. Intravenous Foreign Protein in the Treatment of Psoriasis.—Francis J. Scully gives a report of eight cases of chronic psoriasis treated by this therapeutic measure, which had responded slowly or were resistant to other forms of treatment. The treatment was conducted in the Cook County Hospital, Chicago, where the patients remained during the entire course of therapy. The foreign protein employed was typhoid vaccine prepared from an active culture, grown twenty-four hours on agar slants, washed off with saline solution, killed by heating at 70 C. for two hours, and preserved by the addition of 0.5 per cent. phenol. It was diluted so that each cubic centimeter contained 100,000,000. From three to five injections were given at intervals of from three to four days. The average dose was from 75,000,000 to 100,000,000, the same dose being used for the succeeding injections as for the initial injection. Following the third injection, 2 per cent. chrysarobin ointment was applied daily to the lesions on the body, and 5 per cent. ammonated mercury ointment to the face and scalp. No internal medication was given. The reaction following the vaccine was similar to that observed in acute articular rheumatism, except that the rise of temperature and the leucocytosis were not so marked. The succeeding injections were followed by a less marked reaction than the preceding injection. The maximum rise of temperature was to 103° F., and the maximum leucocytosis was 1,600. Headache was noted in two cases, and nausea and vomiting in one case. No other ill effects were observed. He offers his results as follows: (1) Intravenous vaccines alone do not clear up the lesions of psoriasis, though they do lessen the induration and inflammatory reaction. (2) When used in conjunction with weak chrysarobin ointment, the lesions clear up rapidly. (3) Favorable results were obtained in chronic generalized cases resistant to other forms of treatment. (4) Chrysarobin dermatitis is prevented by the vaccine, and when present yields promptly. (5) The action of the vaccine is not fully understood, but it seems to lessen the sensitiveness of the skin to local medication, allowing uninterrupted treatment.

1. The Harveian Oration: Harvey's Work Considered in Relation to Scientific Knowledge and University Education in His Time.—Robert Saunby delivered this oration before the Royal College of Physicians of London on October 18, 1917. In referring to the impulse given by Harvey to British physiology he states that there can be no doubt that in the sixteenth and seventeenth centuries those Cambridge men who desired to study scientific medicine could not do so at home, and resorted to the Italian universities to study under such great masters as Vesalius, Fallopius, and Eustachius, whose success was rather in descriptive anatomy than in physiology. Harvey's work was of great importance because, although he added no new facts, he placed a new interpretation on what had been more or less common knowledge for 2000 years, and stimulated an advance in medicine which has continued up to the present time. This advance was mainly due to his employment of vivisection, by which method he laid the foundations of physiology and thereby of the progress of medicine. Physiology has been rightly called the Institutes of Medicine, which must march hand in hand with pathology and be its guide. Its progress depends upon the advance of many sciences, especially of chemistry, in that department which we call organic or physiological. This was a new science 40 years ago, and has been built up within the lives of many of us. It has opened out a wide prospect and gives promise of revolutionizing medical study.

The impulse that the work of Harvey gave to British physiology is shown by naming those who followed him in the next 100 years.

4. Ether-oil Anesthesia by the Rectum.—H. M. Page states that this method of producing anesthesia originated from James T. Gwathmey of New York. While employing it in operations of the thyroid gland when hyperthyroidism was present, after 1914 he began to use this method for the wounded in cases of plastic face and jaw operations. Some fatalities have occurred in this particular class of case under the ordinary methods of anesthesia. He therefore advises the more frequent use of Gwathmey's method, which is simple, easy, and he believes, safe. The apparatus required is very simple: An indiarubber catheter; a funnel; a medicine measure; an empty medicine bottle with a cork, to shake the mixture in—this shaking must be done forcibly for two minutes. The following is the technique employed: A simple wash-out of the bowel an hour or two before the injection, in addition to the usual preliminary dose of medicine, is an advantage, but can be dispensed with if necessary. A subcutaneous injection of morphia gr. ¼, atropine gr. 1/100, is given half an hour before the time fixed for the ether-oil injection. He has used the paraldehyde rectal injections, but prefers morphia subcutaneously. From 20 to 25 minutes before the time of operation 6 ounces of a mixture containing two parts of ether to one of oil (ether 4 ounces, oil 2 ounces) are slowly run into the rectum. Six minutes are spent in making this injection. The indiarubber catheter is passed 3 or 4 inches into the rectum, never more than 4 inches. When the operation is finished the remaining ether-oil must be washed out, using a large rectal tube and funnel. The wash-out must be done thoroughly and methodically, as on this depends the rapidity with which the patient recovers consciousness The tube is gradually passed up and as much as possible of the remaining ether-oil mixture withdrawn. The tube is then drawn down again near the anus, and some water or saline is run in and siphoned off. This is repeated gradually higher up the bowel until no oil or ether can be detected in the returning fluid, when the tube is gradually withdrawn lower and 3 ounces of olive oil are passed in and left there. The temperature of the water or saline must not be above that of the rectum—in fact, only the chill off. Following the use of this technique there have been no rectal, pulmonary, or gastric sequelæ. The return of consciousness is not delayed when the washing out is done satisfactorily. He says that soldiers, unless they are very ill, are resistant to the effects of ether, and there is also the loss of ether in the breath, from the venous blood as it passes through the lungs, so that to procure a full anesthesia in a reasonable time it is often necessary to administer a little ether with a Clover's apparatus and allow some rebreathing; if preferred, either by the open method or some A. C. E. can be given. If it is not possible to give the injection 20 minutes before the time for operating some anesthetic vapor by the mouth will certainly be necessary for induction to prevent delay. He has used this method in face, mouth, and nasal operations 17 times; they all made uninterrupted recoveries, and there were no rectal or other sequelæ. This is not a large number of cases in itself, but he has used ether-oil rectal anesthesia in 47 cases altogether. The operations in which he has used this method are as follows: Plastic operations on the face, operations on the jaw, radical cure of antral disease, esophagoscopy, bronchoscopy, laryngoscopy, removal of nasal septum, cholecystotomy, cholecystectomy, gastrostomy, gastroenterostomy with partial gastrectomy, exophthalmic goitre, laminectomy, trephining, appendicectomy, amputation of the breast. All these 45 cases recovered from the operation except 2. These 2 cases were laminectomies; they died some time after the operation from ascending myelitis. In 2 of his early cases, in which a 75 per cent. solution of ether was used, there were rectal irritation, mucus, and a slight trace of blood lasting a day or two. In another case there was looseness of the bowel for a couple of days; since then he has never used a stronger solution than 2 to 1, as recommended above. Mower White adds a word in recommendation of this method in which he states that the results have been uniformly good both as regards the condition of the patient during the operation and as regards the absence of untoward symptoms afterwards.

3. Modern Artificial Limbs and Their Influence Upon Methods of Amputation: General Consideration. E. Muirhead Little. Demonstration. R. C. Elmslie.

3. Modern Artificial Limbs and Their Influence upon Methods of Amputation. General Consideration.—E. Muirhead Little states that at first sight it may seem this subject is being considered with an implication of putting the cart before the horse; that the artificial limb should be influenced by the amputation which calls it into being, and that the converse should not occur. In order to produce good results the surgeon and the limb-maker must have some knowledge of each other's limitations. The surgeon should not design and carry out an amputation to which an artificial limb cannot conveniently be attached. On the other hand, it is useless to devise a limb if it could not be borne by the patient's stump. Conditions of the problem differ in the upper and lower extremities. In the lower extremity the functions of the lost part are crude compared with the delicate and nicely-adjusted and co-ordinated movements of the upper extremity. Its chief duties are to support the weight of the body at rest and in motion and to act as the propellent force in the process of locomotion. End pressure and leverage are the strains to which it is most exposed. The upper extremity is mostly employed in prehension and traction-functions to which the foot of boot-wearing man is a stranger, and end pressure, therefore, is not one of the most important strains to which it is exposed, while leverage is all-important. As the movements of the hand and fingers are highly coordinated and often very delicate, it follows that the problem here is a very difficult one. The best artificial arm and hand is but a poor substitute for the living member, while the artificial leg can be made to do nearly everything that is required of its living predecessor—to do it, that is to say, more or less, though not so well as the latter. In both extremities provision has to be made to maintain the appliance in place when in action and when in rest against the force of gravity. Weight is borne in two ways. Often or generally combined—(a) by direct pressure of a part of the body downwards, such as the

end of the stump, or of a convenient bony process, such as the tuberosity of the ischium, or (b) by oblique pressure, when the artificial socket forms a more or less conical cavity into which a conical portion of the body fits. Leverage is exerted by the lateral surface of the stump pressing against the side of the surrounding socket. An ideal amputation stump would be as long as possible, it would be covered by sound movable parts, and the scar would be placed in a position where it would not be exposed to pressure, and it also would not be adherent to the bone. It would have enough muscles attached to it to move it with adequate force, and no inflamed or hypersensitive nerve ends would be palpable in it. The end or ends of the bone or bones would be rounded so as not to hurt the soft parts under them, and the blood supply would be free and the skin well nourished. The well known objections to exarticulation are given. An analysis of the records of 549 cases of amputation of the lower extremity seen recently at Roehampton shows that in 275 of these—almost exactly half—it was found advisable to fit an end-bearing pad. As might be expected, the proportion varied widely in the different regions. In the upper third of the thigh only 9 per cent. were thus fitted, in the middle third 32 per cent., in the lower third 77 per cent. It was found that the stumps in the lower third of the thigh are more sound than those in the upper and middle thirds, which latter region is the seat of nearly half of the total number (43 per cent.). The surgeon who has to deal with many of these end results cannot fail to be struck by the prevalence of wide adherent scars in the upper two-thirds of the thigh. Some of these, not many, are unmodified guillotine operations; the majority are not, and many are, the results of later operations in which attempts have been made in vain to produce a stump covered by sound skin. Some of these unfortunate persons have suffered as many as seven amputations on the same limb. In the upper extremity the question of end pressure does not arise, and here the condition of the lower part of the anterior and external surfaces of the stump is of most importance, because these surfaces have to take much of the pressure of the leverage action on the bucket. Many arm stumps with large adherent guillotine scars covering the end of the bone have been found to be quite satisfactory in practice. The presence of osteophytes is rarely any hindrance. These are seldom large, except in the thigh, and then they are usually situated about the femoral insertions of the adductor muscles, which are not exposed to much pressure.

Le Progrès Médical.

September 22, 1917.

Spontaneous Rupture of the Heart from Atheroma and Thrombosis of the Anterior Coronary Artery.—Tapie reports the case of a soldier aged 49, never ill before the war, vigorous, without taint, who presented a hypersonorous percussion note with subdulness over the bases, effort dyspnea, and subscrepitant rales over upper regions of both lungs. He complained of intermittent asthmatic crises with suffocation, slight cyanosis, expiration, dyspnea, and orthopnea. Temperature subfebrile, pulse 90. Shortly after admission he developed asystolia—edema of ankles, irregular pulse, and diminished urine, with albuminuria. He was improving under cardiotomics, when, upon rising from his breakfast, he collapsed and expired. The autopsy, held 22 hours after death, showed externally only edema of the lower extremities. There were bilateral pleural adhesions and hydrothorax. The lungs showed some emphysema with edematous congestion of the lower lobes. Pericardial sac greatly distended with fluid blood and clots "as if patient had been bled" into this cavity. There was no lesion of the great vessels and no aneurism. The hypertrophic, spheroidal heart showed an area of softening in which were visible two tears. There was an enlarged, congested nutmeg liver. The kidneys were congested but peeled readily. The heart was the only viscus to require a detailed description. The hypertrophy was limited to the left ventricle. Upon section the myocardium was firm, greyish and sclerotic, cutting with difficulty. The softened area represented an infarct toward the apex, triangular, with base 7 to 8 cm. in width. In addition to two ruptures directly into the ventricle there was a third, blind opening. The left auricle was slightly dilated with the lesions of sclerous endocarditis near the mitral. The left ventricle was dilated with pillars thickened and a little sclerosed. The softened area was surrounded by sclerotic tissue. The right heart by contrast was notably normal. The aorta, slightly dilated, was of the consistency of cardboard, with areas of atheroma throughout its extent. The aortic valves were normal as to function but exhibited traces of sclerous endocarditis, as did the subjacent endocardium. The orifices of both coronaries gaped and were free from atheroma. The right vessel was permeable while its fellow was notably atheromatous, especially in its two branches. There was no narrowing or thrombosis in the main trunk nor two main branches: only the anterior descending ramus showed at its lower third the condition which explained the mechanism of death. It was not completely obstructed but the walls were thickened and atheromatous with an obliterating thrombosis beneath the infarction. The condition is extremely rare, even in the aged, and in a vigorous man in middle life almost unique.

The Foot Stasis of the Trenches.—Renard and Blum apply to the socalled trench foot the term stasis or stagnation foot of the trenches. The causal factors are prolonged standing plus constant exposure to mud or cold water. In most cases the feet swell and are painful for a few days; after which the symptoms subside save for vague suggestions of neuritis. In other cases phlyctens appear with serous or blood-tinged contents. For a long time this affection was held to be nothing but frostbite; and it is true that exposure to cold alone can cause gangrene of the immobilized feet—a dry gangrene. This, however, is a special form of exposure. But a chilled foot is not a frozen foot, nor is the question one of relative temperatures. A trench foot can be initiated by simple exposure to cold, but other factors as humidity and constriction of the legs may be involved. Certain authors believe that the condition is one of infection which has its début about the toe nails, or in chafes, etc. The theory is ingenious and derives some support from animal experiment, but actual inspection shows that in the great majority of cases there is absolutely no evidence of infection or even of an abrasion which could serve as a port of entry for germs. Standing in water in summer does not produce anything like trench foot, yet a study of the dirt about the toe nails would show an abundant flora. Nor is trench mud the sole cause of trench foot, for artillerymen sometimes present the same lesion. The authors describe a typical case of trench stasis. Soldier, infantry, age 29, entered a trench April 21. This trench was relatively shallow yet the water in it came to the ankles. The soldier's station was directly under fire and he could not budge an inch more than necessary. He stood but little and for the most part sat or kneeled. For four days he did not complain, but after that he shivered with cold and his feet were cold. This sensation increased until it became painful, so distressing in fact that the soldier wept. But these sensations gradually ceased as the feet swelled and throbbed. After this period pain appeared only in crises. The feet felt dead and the patient soon became unable to walk. When he trod he felt pins and needles. Removed to a dressing station, examination showed a swollen foot, violet red on the dorsum, macerated. The great toe and fourth toe were white, livid. Between the second and third toes there was a large phlycten which contained a pinkish fluid. These symptoms receded save for the lividity of the toes. Later the patient complained of severe lancinating pains in the heels and toes and was unable for that reason to stand. At night, in bed, they were also severe and radiated upwards along the legs and thighs. There was slight edema of the ankles. The great toe was insensible. Finally the swelling of the foot subsided but the affected toes showed a trace of dry gangrene. The eschars did not come away for 12 days. The entire tip of the fourth toe was lost. Aside from lancinating

pains at intervals the patient has completely recovered. The authors analyze this case with extreme thoroughness. While suggesting a frost bite the entire history of the case indicates the existence of an arrest of circulation. The component of stasis must be distinguished from the component of cold. Stasis is evident at first from the mild edema, and later from the livid color. A higher degree causes the phlyctens at the base of the toes, a still higher one causes superficial sloughs and finally there is slight sloughing *en masse*. The cause of this circulatory stagnation is compression by the boots. The only prophylaxis is removal of the latter as soon as the symptoms of stasis appear. They should be replaced by some soft covering, even bath slippers. Experience teaches that with such footwear soldiers can march even through cold mud or water without the development of stasis foot. In cases in which phlyctens have not yet formed it is only necessary to raise the foot of the bed and make use of sunlight or hot air; the latter in connection with an apparatus devised by the authors, which causes profuse sweating. If ulceration has developed antitetanus serum must be injected. Eschars and gangrene require ordinary surgical measures.

The Effort Test of Tachycardia.—Aubertin refers to some of the resources in use for testing the action of the heart through induced tachycardia. His own method is based upon that of Martinet and Lian who after a given effort take the blood-pressure and pulse. He provokes effort-dyspnea by muscular exertion, effort-tachycardia by the same resource and finally notes the degree of cardiac acceleration produced by standing. The results thus obtained are constant in normal subjects. Patient is examined at a time in which digestion is believed to be quiescent, *i.e.* not long before meal time. The pulse is now counted until the emotional reaction is found to have disappeared (from 3 to 10 minutes), the patient being recumbent. He then stands up with muscles not tense and his pulse is taken over a period of 3 minutes, after which he lies down for a second recumbent count. He now exercises in his socks in some manner which can be controlled and measured for one minute, after which his pulse is at once taken. He then lies down for the same purpose. In this position his respiration is also noted. The various pulse rates are charted in curves. Two maxima correspond to the rate on simple standing and after exertion, but the latter varies greatly with the character of the effort. The mere acceleration proves nothing for the test is really meant to ascertain the length of time required for the heart to reach its normal frequency. In the normal subject we sometimes see a "reaction-bradycardia." Subjects with organic disease who have good compensation may react as normal subjects because the test is not of the patient *per se* but of his circulatory apparatus. On the other hand, subjects with a very marked tachycardiac reaction may come to equilibrium during the normal interval. When tachycardia persists and remains high for a prolonged period—this is a rare phenomenon—the cause may not be apparent.

In theory the myocardium should be weak and easily dilatable but if such is the case why is it not the rule in uncompensated organic heart disease? Transitory arrhythmia due to extra systoles is seen after the subsidence of effort tachycardia. The clinical value of the test lies as already stated in the length of interval required for equilibrium which in the great majority of cases is reasonable and not paradoxical. The value of the method consists in part in its simplicity, for no apparatus is necessary—the blood-pressure is not taken and even the stethoscope is not required save in the special case.

Studies in Comparative Anatomy of the Musculus Palmaris Brevis.—Kajava communicates his observations on the occurrence of the palmaris brevis and flexores breves manus in the vertebrates including 82 different species of mammals from nearly every order. There is also a description of the hand with special reference to the ulnar carpal fixation with which the musculus palmaris brevis appears to stand throughout in intimate connection. The author enhances his own observations with references from the special literature. The investigation gives the following results: The muscle in question is absent in the lowest mammals (monotremata, marsupials, and insectivora as well as the non-climbing edentates) although in individual cases it is present in marsupials and insectivora. In the rodents, the climbing edentates, the carnivora and prosimians, as well as in most apes, it is well developed; but in the anthropoid apes and hylobates it is weakly developed or absent. In the chiroptera, pinnepades, cetacea, sirenes and ungulates it is absent because of a peculiar differentiation of the hand. The muscle is constantly associated with the ulnar carpal fixation and functions as a motion muscle for the same, which in many cases offer a counter-support in the grasping of objects with flexed fingers. In addition to these there are other balls, especially the radial carpal, which can sustain a moving muscle. The m. palmaris brevis presents a subdivision of the most superficial bundle of the original common mass of flexor muscles of the hand and stands in genetic relationship most closely with the Mm. flexores brevis. Like the latter, its nerve supply is derived from the superficial volar branch of the ulnar nerve. The investigations of Retzius, Schlaginhaufen, Wilder, and others, show that there is in man at the basis of the hypothenar a residue of the ulnar carpal ball which corresponds to the site and insertion of the palmaris brevis. By reason of this behavior we may conclude that in man there is not only a residue of the ulnar ball, but also a movement of the muscle which serves this ball—the musculus palmaris brevis.

Excessive Proliferation of the Chorial Epithelia in a Case of Repeated Tubal Pregnancy.—Maunu af Heurlin states on the basis of the official statistics that the frequency of vesicular mole varies from one case in 5,000 to one case in 10,000 labors. On an average a population of 200,000 will produce one annual case of vesicular mole. In about 5 per cent. of cases of the latter malignant choris epithelioma should develop, so that in a community of 2,000,000 inhabitants with 60,000 annual childbirths there should be one case of this affection. The author describes a case of ovarian pregnancy in the first month in which the proliferation of chorial epithelia was so excessive that the probability diagnosis was malignant chorio-epithelioma. However, eight years after the operation the patient remains well. The pregnancy developed in a tube in which 1½ years before a tubal abortion had occurred, as shown by laparotomy. Microscopically the condition was identical with a case of vesicular mole in which clinically there was a distinct vaginal metastasis. This patient, too, remains well—after seven years.

Benign Dropsical Beriberi.—Fiessinger and Lecuyer agree with certain predecessors that the dropsy in the mild beriberi syndrome is due to chloride retention.—*La Presse Médicale.*

Determination of Sex.—Regnault suggests to experimenters that they take up experiments based on injection of lipoids and internal secretions with especial reference to femaleness of offspring.—*La Presse Médicale.*

Leprosy in the Senegalese in France.—Before the Réunion médico-chirurgicale of the VIII army last June, Joltrain cited a case of mixed leprosy in a Senegalese rifleman. The infection naturally antedated the trip to France. The victim had left a leprous sister in Senegal. Spillmann also reported a case of anesthetic leprosy in a native Senegalese rifleman.—*La Presse Médicale.*

Effects of a Potash Poor Diet.—According to Urbeanu animals fed on a potash free diet develop disturbances of the beriberi type. After 30 years' observation of Roumanian pellagra he believes that the maize factor in the etiology can be explained by its low mineral content. But the potash exists in organic combinations, so that something more is present than a mere mineral starvation.—*Office International d'Hygiene Publique.*

Book Reviews.

THE DESTINY OF THE AMERICAN SURGICAL ASSOCIATION. By J. EWING MEARS, M.D., LL.D. Reprinted from the Transactions of the Association, Vol. XXXV, 1917. Philadelphia: Wm. J. Dorman, 1917.

THE author of this interesting brochure is one of the three surviving co-founders of the Society. S. D. Gross, who is dignified as the sole Founder, receives an appreciation in connection with his official acts. The Society has now existed for thirty-seven years and has thirty-four volumes of Transactions. Characteristic of this body of men is the great attention paid to experimental surgery, and the destiny in part of the Society is foreshadowed in the hope that through its activities the problem of malignant disease will be solved and at the same time that mutilating surgery will in time give way to a strictly conservative science.

POETRY AND THE DOCTORS. A Catalogue of Poetical Works Written by Physicians with Biographical Notes and an Essay on the Poetry of Certain Ancient Practitioners of Medicine. Illustrated with Translations from the Latin and by Reproductions of Title Pages of the Rarer Works. By CHARLES L. DANA, A.M., M.D., LL.D. Price, $5.00 postpaid. Woodstock, Vt.: The Elm Tree Press, 1916.

MEDICINE is the art which endeavors to reproduce harmony in the body; poetry is the art which produces harmony of thought by means of measured word and line. Since both arts have the common aim of harmony as the reason for their existence, is it a matter of surprise or wonderment that medical men should possess both arts?

Rather is it to be expected that these men should turn to the satisfying field of verse as a channel through which can flow in measured way that which may baffle them in their endless encounter with the human unknown. Has anyone ever thought that the most commonplace physician lives a life bound up in poetry? Poetry of living by the daily endeavor to harmonize other lives.

The author of this slender volume of "Poetry and the Doctors" brings out this fact, since he has gone back to the poetical works of physicians of ancient times, of those who contributed to Latin and English verse, as well as some examples of the poetry of Italian, German, and French physicians. His researches have been made over a literary period of two thousand years. He states in an introductory essay that the authors have one thing in common: they were all supposed to be authorized and able to write the sign of Jove. The book carries the reader through the medical poets of the nineteenth century.

Under the name of each poet is given, besides his writings, a short biographical sketch of the man. Added to these are twenty-one half-tones showing early title pages, early printing, first editions, and early forms of book-making.

Truly and delightfully original in its conception, Dr. Dana acknowledges that the compilation of this beautiful work has brought to him many hours of unexpected pleasure. So, too, will it bring to the readers, not only through the knowledge offered, but through the grace of the style, the beauty of the English, and the faithful and artistic reproductions of the old title pages. The general make-up of the volume justly adds to the credit of the press which produced it.

Dr. Dana has offered a work of love, love for a profession, which certainly will bow in graceful acknowledgment for so beautiful a gift to its members.

MODES OF RESEARCH IN GENETICS. By RAYMOND PEARL, Biologist of the Maine Agricultural Experiment Station. Price. $1.35. New York: The Macmillan Company, 1915.

"ALL knowledge is potentially useful, but the fundamental reason for undertaking and encouraging research in genetics, or anything else, is not because what one gets may be immediately useful, but because it is *knowledge*." Too true a statement by the author of this little volume, in which he outlines the underlying methodological bases of modern genetic science. Some of the material here presented has already found readers through the pages of other scientific journals, where awakening an interest and enthusism, it has led to the publishing of the present work.

Since the science of genetics is just beginning to open its eyes to the light, every phase of truth regarding it must be thoroughly studied and investigated before it can be accepted as an established fact. Even though conclusions apparently can be drawn through heredity, the forces of environment and the further known action of certain parent cells in the exhibition of traits in the young, Pearl states that "one can experiment in regard to one's progeny, but not in regard to one's ancestors."

The book offers "A critical examination of current modes of research in genetics," "Biometric ideas and methods in biology: their significance and limitations," "On the nature of statistical knowledge," "Certain logical and mathematical aspects of the problem of inbreeding," and "Genetics and breeding." The author shows a depth of wisdom and exceedingly tolerant breadth of view when he hopes that, even though the reader may disagree with the subject matter and conclusions here offered, if an interest has been aroused sufficient to lead to further thought and study of this matter, the book will have served its purpose.

THE CHILD IN HEALTH AND ILLNESS. By CARL G. LEO-WOLF, M.D. Illustrated. Price, $2.00. New York: George H. Doran Company, 1917.

EVERY new book that is published for mothers on the care of infants and young children usually marks an advance in the practical knowledge offered in the most important field for women this old world holds, that of motherhood. This book, of moderate size, shows what an improvement has been made by pediatrists in the manner in which they have presented their all-important knowledge to the laity. It is really written from the standpoint of the mother and not entirely from the standpoint of the child. Hours of labor are saved the woman by timely suggestions as well as by the practical knowledge contained in every "mother and child" book.

As one reads, there comes a realization that this author is writing in a manner so sympathetic in his appreciation of the confusion and uncertainty necessarily associated with the first days of motherhood that a feeling of confidence and relief must come to the mother who will depend on this book for the unravelling of the many snarls of the first year particularly.

Sensible, clear-cut illustrations are included; also a set of weight charts, weekly for the first and second years, and also one for use from the first to the fifteenth year.

OBSTETRIC AND GYNECOLOGIC NURSING. By EDWARD P. DAVIS, A.M., M.D., F.A.C.S., Professor of Obstetrics in the Jefferson Medical College, Philadelphia; Obstetrician to the Jefferson Hospital; Obstetrician and Gynecologist to the Philadelphia Hospital; Consultant to the Preston Retreat; Member International Society Obstetricians and Gynecologists; American Gynecological Society, etc. Fifth Edition, thoroughly revised. Price, $2. Philadelphia and London: W. B. Saunders Company, 1917.

THIS well known work has been revised throughout and is in its present form a most excellent reference book with respect to all that concerns obstetric and gynecologic nursing. It may be strongly recommended to the profession as such.

OBSTETRICS, NORMAL AND OPERATIVE. By GEORGE PEASLEE SHEARS, B.S., M.D., Professor of Obstetrics and Attending Obstetrician at the New York Polyclinic Medical School and Hospital; Formerly Instructor in Obstetrics, Cornell University Medical College; Attending Obstetrician at the New York City Hospital; Senior Attending Obstetrician at the Misericordia Hospital, and E. E. SHEARS, M.D. 419 Illustrations. Second Revised Edition. Price, $6. Philadelphia and London: J. B. Lippincott Company, 1917.

THIS book represents a phenomenon which must be extremely rare in medical literature—a second edition of a posthumous work (at least the author died before the book was published) fifteen months after the appearance of the first edition. This fact speaks eloquently for the excellence of the work, which we reviewed with full appreciation at the time.

Society Reports.

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eleventh Annual Meeting, Held in Newburgh, November 9, 1917.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. RICHARD GILES OF COLD SPRING, IN THE CHAIR.

Address by the Secretary of the Medical Society of the State of New York.—Dr. FLOYD M. CRANDALL made a brief and informal address in which he told of the thriving condition of the State Society and the interest taken in the District Branch meetings. He said he knew his hearers would be glad to learn that the President of the State Society, Dr. Alexander Lambert, was doing an excellent work in Europe. He was the medical adviser of the relief work in France and Belgium, a very responsible position, and one that involved the handling of vast sums of money. He had heard quite indirectly from a person conversant with the work that the one man who stood head and shoulders above everyone else in efficiency and executive ability was Dr. Alexander Lambert. Dr. Crandall then emphasized the importance of the district branches as parts of the Medical Society of the State of New York, and said that it was essential that their presidents be chosen with careful discrimination. This was because the office of president of a district branch imposed three important duties. A man in virtue of his position as president of a district branch was also a delegate to the House of Delegates of the State Society; a member of the Council of the State Society, which was the executive body of the State Society in the interim between meetings, and a member of the Board of Censors of the State Society. Dr. Crandall described the duties that devolved upon the president of a district branch in each of these capacities and urged that in order to make his work more effective he should make at least one visit each year to each county society in his district.

Is It Syphilis or Not?—Dr. WILLIAM S. GOTTHEIL of New York presented this contribution. He said that it was the purpose of his paper to lay down broad general principles for the guidance of the practitioner in his daily work. In his opinion no test tube and no microscopic slide could, in most cases, take the place of the older, readier, and usually more reliable methods at everyone's disposal. But it might be argued that a clinical diagnosis of the proper kind presupposed an amount of experience and skill that was not at the disposal of every practitioner; this proposition he was not ready to admit, save in exceptional cases. How much easier, it had been said, was it to send your specimen to the laboratory and have the diagnosis returned to you by mail. Perfectly true, it was easier, but it was often neither certain nor safe, and it might lead to errors that had lamentable consequences. As to the blood or Wassermann test—When the syphilitic virus had overcome the barrier of the chain of lymphatic glands nearest the site of infection, it occasioned certain alterations in the blood which might be manifest in the test tube. This process, however, took from four to six weeks on the average. During this period the patient, already infected, showed no signs of the disease. This was most unfortunate, since it was the most critical time of all for the patient, being the period during which the most effectual efforts might be made to cure his disease. On the other hand, the blood changes that gave us the Wassermann reaction, once established, might last indefinitely; in fact, in the great majority of cases they did last indefinitely. Other signs and symtoms must therefore be relied upon for making a diagnosis. A positive Wassermann reaction simply meant that the patient at some time or other in his life, before or after birth, had had a syphilitic infection. It did not mean that the condition under consideration was syphilitic. It might be an indication of value in handling the patient, but it was distinctly a subsidiary element in the diagnosis, which must be made on other evidence. Very much the same considerations held good for microscopic examinations of smears and sections. Those who had had personal experience with these procedures would, the writer felt sure, be the first to admit that, helpful as they might be in certain cases, the incidents of microscopic technic and the personal equation of the examiner played a rôle so important that the evidence thus obtained must be regarded as helpful and subsidiary rather than as determinative. This was especially true of skin sections. There was, however, a differentiation in the value of evidence which was often lost sight of, namely, that a positive finding, serological or microscopical, at the hands of a competent observer, had a definite value; a negative finding, on the other hand, was much less important, because of the possibility of faults of technique, accidental features, and the personal equation. The essayist then called attention to a few of the commoner and more important instances in which the question came up "Is It Syphilis or Not?" With reference to the *chancre* and the lesions that resembled it—chancre was usually an insignificant, painless, single tumor, with erosion and ulceration, if present, secondary and accidental; characteristic stony hardness; characteristic local adenopathy. Spirochetes were found in the scrapings, and appeared weeks after intercourse. The lesion was usually accompanied by other signs of syphilis in the organisms. *Chanroid* was a very painful and tender, single or multiple lesion, with small circular ulceration and no induration save a slight inflammatory one. It appeared a day of two after infection. The neighboring lymph glands were doughy, swollen, tender, and prone to suppurate. No spirochetes were present as a rule and there were no signs of early constitutional syphilis. It usually appeared in the young and signs of past syphilis might or might not be present. *Gumma* usually appeared as single or multiple doughy painless tumors, usually secondarily infected and ulcerated. It had no relation to intercourse. There might be painless local adenopathy, but no general adenopathy. The blood was usually Wassermann positive; spirochetes usually were not found locally. The signs and history of past syphilis were present. This lesion might occur at any age and last indefinitely. Herpes was characterized by small, circular, itchy vesicles, or erosions running their course and disappearing spontaneously in a few days without trace. There was no induration, ulceration, or characteristic local or general adenopathy. There was a history of past similar attacks. No spirochetes were present. The signs of past or present syphilis might or might not be present. It occurred at any age. *Cancer* showed a moderately painful and tender tumor, ulcerated, usually single, and in the aged. It had usually run a course of many weeks or months. It was never suppurating. No spirochetes were present.

The signs of recent or old syphilis might or might not be present. The microscopic examination was often decisive. The essayist then reviewed the differential points between the secondary syphiloderm and the eruptions that resembled it with special reference to psoriasis, and the differential points between the tertiary syphiloderm or gumma and the lesions which resembled it, cancer and lupus vulgaris.

He very strongly emphasized the point that the syphilographer must be in the first place a dermatologist, since the diagnosis "Is It Syphilis or Not?" must in nine cases out of ten be made from a non-syphilitic lesion of the skin or visible mucosa.

Dr. MIHRAN L. PAROUNAGIAN of New York, after complimenting Dr. Gottheil on the selection of his title, his good judgment in the selection of the palpable points in the differentiation of syphilitic lesions, and his very interesting photographs, said he heartily agreed with the statement that in order to make a correct diagnosis of syphilis a man must be a dermatologist, because syphilis was one of the greatest imitators of a variety of skin diseases, such as psoriasis, lichen planus, lupus, and a variety of other skin diseases. In order to be able to make a correct diagnosis of syphilis one would have to be acquainted with other forms of cutaneous disease. It was true that so far as the Wassermann reaction was concerned it was carried a little too far, as Dr. Gottheil had said, especially among the younger members of the profession. The Wassermann reaction was just like any other technical procedure; much de-

pended on the accuracy of the technique. In the speaker's opinion the Wassermann test was a very valuable procedure for the general practitioner to have recourse to since he was not familiar with all forms of cutaneous manifestations. It was true that the Wassermann might be negative in some cases of syphilis and that a negative reaction did not always mean that syphilis was absent, but on the other hand a positive reaction could generally be depended upon to indicate the presence of syphilis, so that it would seem that this was coming pretty close to enabling one to make an actual diagnosis. If one was not thoroughly familiar with the technique of the dark field, India ink, etc., he should make repeated Wassermann tests and he would find them really a great help in diagnosis. Just as in typhoid fever cases the Widal reaction would be found present for many years, so with syphilis, it was very difficult to change a positive Wassermann that had persisted for a considerable length of time. The speaker was of the opinion that if one found a strongly positive Wassermann it meant something: it meant the presence of a certain amount of dynamite in the system which some time or other might explode. It was always a danger signal. Where such a positive reaction was found every effort should be made to make it negative and to keep it so. If one did not succeed in making a positive reaction negative in a few months or a year or so, it was very difficult to make it negative and keep it so. One should not allow a four plus Wassermann to go untreated and to say that the patient would probably be all right, for 94 per cent. of old syphilitics showed aortic involvement, or involvement of the spleen, heart, or some other viscera. An early diagnosis and early treatment would save the unfortunate results so often witnessed in our neurological clinics. Another point was with reference to extragenital chancres. One might find these on the back of the washerwoman's hand, in a case of surgical injury, etc. The speaker cited a case in which a man had received an injury and was treated for two or three weeks in a hospital before it was found that he had been infected with syphilis at the time he received the injury. Another way in which the infection might be transmitted was by biting. One case coming under his observation showed a chancre at every point where a tooth had penetrated the skin. They had been taught that genital chancres, as a rule, were single lesions, but they were seeing more multiple chancres than ever before and it would be better to discontinue the teaching that they were single. As to chancroids, this form of lesion should be followed for several months, for too often the diagnosis of soft chancre and a failure to give specific treatment resulted in the subject going to the neurological clinic later with some involvement of the spinal cord or brain.

Dr. Gottheil, in closing, said he wished simply to touch on one practical point and that was whether a positive Wassermann reaction was an indication for active anti-syphilitic treatment. He thought that depended entirely upon the patient. In an institution with which he was connected they sent wayward girls with positive Wassermann reaction for treatment. If the girls were sent back without treatment they were returned to the institution. These old positive Wassermann reactions would remain positive in spite of all treatment among this class and one would have to have ten city hospitals to care for these patients. With the private patient the situation was different and one should make every effort to sterilize the blood by a proper course of treatment, and once in a while one would be successful, but in the ordinary patient among the poorer classes the attempt to render a long standing positive Wassermann negative was useless.

The Signs and Treatment of Thyroidism.—Dr. John Rogers of New York presented this communication. He said that he based his remarks upon an experience of 448 cases of thyroidism in which he had operated. The general aim of the operations was to protect and save rather than to excise or destroy thyroid tissue. The operations had been guided in this aim by a hypothesis which assumed a close relationship in the causation of all types of thyroid abnormalities. Every kind of thyroid disorder seemed to be preceded or accompanied by circumstances which manifestly or by inference involved fatigue. There followed an enlargement of the thyroid which seemed to be an hypertrophy to compensate for excessive demands upon the thyroid function. From this point the later progress of the disease was (1) toward a quiescent simple goiter with greater or less degenerative changes in the gland, (2) toward hypothyroidism and into myxedema, (3) toward hyperthyroidism, and finally (4) toward exophthalmic goiter. The presence of exophthalmos seemed to mark a more dangerous stage of the disorder than the preceding signs of simple hyperthyroidism. Any one of these conditions, especially the quiescent goiter, could at one time or another change its symptoms under favorable or unfavorable circumstances and show the signs which were supposed to indicate any opposite extreme of thyroid function. Hence, in the title of this article there was used the term thyroidism. The most characteristic, if not the only, symptoms of these apparently different disorders were referable to the involuntary nervous system. Fatigue was known to affect the terminal filaments of nerves, and it therefore might be necessary to include in this fatigue hypothesis for the thyroid, an additional fatigue of the terminals of one or another part of the involuntary nervous system. As yet, however, from a therapeutic standpoint, this introduced an unnecessary complication.

Physiology.—It should be recalled that the involuntary nervous system consisted of two parts which, broadly speaking, seemed to have opposing functions. One of these parts was called the autonomic group of nerves, and was in general stimulating or "activating," the other was the sympathetic proper or "inhibiting" group. Every organ in the body, except the brain, was apparently supplied by a branch from both the activating and inhibiting parts of this involuntary nervous system. As a whole, it seemed to act as a means of coordinating the activities of the different bodly forces and organs. The thyroid was known to be intimately associated with the general process of oxidation, and this process was also concerned in the production of heat and energy. Hence, it was no great step to assume that excessive production of energy and fatigue was the ultimate causation of all of these more or less closely allied thyroid abnormalities.

Symptoms.—Certainly the evidences of marked fatigue, when associated with an enlarged thyroid, were commonly accepted as the symptoms of hypothyroidism. There were headache, pallor, dry skin, anorexia, gassy indigestion, constipation, and low blood pressure. Wakefulness and a subnormal temperature and slow or rapid pulse were common. If the fatigue continued, the symptoms advanced to those of myxedema, or there followed a gradual disappearance of the headache, pallor, anorexia, and constipation. The skin more or less rapidly became flushed and moist, the pupils were dilated, the appetite was good, and the bowels were regular or even loose. The heart action in this early stage was usually exaggerated, pounding or thumping, instead of merely rapid. These signs were all evidences of irritation or activity of the activating rather than the inhibiting part of the involuntary nervous system. Exophthalmos, when it occurred, usually appeared at this period. As these evidences of hyperthyroidism continued, the moist, flushed skin was generally succeeded by one which was dry and pale, and the low blood pressure by one which slowly rose. The exaggerated heart action became one which was merely rapid. The excessive appetite and frequent bowel movements changed to anorexia and constipation. In other words, the picture of hyperthyroidism began with evidences of irritation of the autonomic or vagus or activating part of the involuntary nervous system, and finally passed into one which showed signs of irritation of the sympathetic or inhibitory group.

Experimental.—Dr. Rogers stated that he had for a long time been interested in physiological tests of different thyroid derivatives. None could be found which, when injected intravenously in dogs, produced any appreciable tachycardia. The only portion of a thyroid extract which was active was soluble in alcohol and non-coagulable by heat. This, when tested upon the stomach, showed vigorous stimulation of the terminal filaments not of the sympathetic but of the vagus. Other observations had caused him to believe that the thyroid activated or stimulated the whole autonomic or activating part of the involuntary system. Some

portions of this group of nerves seemed, however, less stimulated than others. An extract of the adrenal made like that of the thyroid seemed, on the other hand, to activate the terminal filaments of the sympathetic.

Treatment.—If all thyroid disorders originated in fatigue and hypothyroidism and advanced from this into the more severe disturbances of myxedema or of hyperthyroidism, then prophylaxis by rest and supporting thyroid feeding were important. As remarked before, he advocated not thyroidectomy, but rather the ligation of vessels with the enucleation, whenever possible, of all diseased thyroid tissue. He had practised in cases of hyperthyroidism the ligation of all four of the chief thyroid vessels in 148 cases. He had had as a result of this operation three deaths. It was more fair, however, to state that he had practised the ligation of one or more arteries in 287 cases of hyperthyroidism, and as the result of this interference there had been 13 deaths. Otherwise, Dr. Rogers stated, no patient had been made worse, and so many had been perfectly cured that he urged the more general adoption of this method. It should, however, be accompanied and followed for a long period by organotherapy. In summarizing, the essayist stated that in all cases of goiter with tracheal stenosis he excised the offending tissue. In all cases of goiter with one or more tumors which were localized, even in the presence of marked hypothyroidism, he enucleated the disease. In all cases of symmetrical goiter which gave more or less severe evidences of hyperthyroidism, especially exophthalmos, he ligated all four chief thyroid vessels in two stages. In all cases of goiter and hyperthyroidism, if the disease seemed confined to one lobe or a part of one lobe, especially if the disease was early or in the vagotonic stage, lobectomy should succeed. Lobectomy would probably fail in all cases in which the symptoms of sympathetic irritation preponderated. Before and for one year after any operation, rest or, rather, good hygiene and appropriate organ therapy were indicated.

Mass Volunteering.—Captain FREDERIC T. VAN BEUREN of New York, of the State Committee of National Defense, made this address. He said he would promise to be neither witty nor eloquent, but he would be brief. The object of his coming to this meeting was that, as secretary of the State Committee of National Defense, he wished to express his appreciation of the work done by the county committees. It was the county committees that really did the work. Any information that came to the State Committee was forwarded to the county committees and they reached the individuals, and it was through the support of the individuals in the county societies that they had obtained results. The work of the medical section of the Council on National Defense was to get a sufficient number of physicians as medical officers. Different men had made different estimates as to the number of men needed, but the point to be impressed on their minds was the uncertainty of the situation. As things now stood they had enough medical officers for immediate needs, but if the war continued for two or three years they would not have enough medical officers. The report had gone forth that the Adjutant's Office had ceased to issue commissions; this was because they had been swamped with applications and had not been able to handle the immense amount of correspondence. It would be necessary for them to take stock and see how many commissions had been granted and how many more officers were needed. In New York State approximately 2,000 physicians had volunteered; that was about one-seventh of the total number of physicians in the State. Eventually about one-third of the physicians in the State might be needed, but that was at present absolutely uncertain. The impression which he wished to leave was that if more men were needed they wanted men of the right kind. Many men in the Medical Reserve Corps were older men, that was, men over 35 years of age, and many had families and important community interests. It was perfectly obvious that the wisest course would be to take those men who were still unmarried and who have fewest community interests, since these could be more easily spared. Attempts had been made to obtain a qualified draft for physicians, but these had been unsuccessful, and it seemed that the only other way to accomplish a proper selection was by shaping opinion in such a way that any man who had no family responsibilities and did not go into the army should be regarded as not doing his duty, and that the man who was needed at home and tried to go into the army should be restrained. The medical profession should make the selection in this way, having it understood that the medical profession and the public considered that the younger medical men without responsibilities were not doing their duty by their country if they did not go into the service.

Dr. S. W. S. TOMS of Nyack said that he had decided to join the Medical Reserve Corps last spring and had been ordered to Allentown. Recruiting of medical men was rather slow at that time. The fact that they had recently been recruiting more rapidly was probably due to the energy, enthusiasm, and patriotism of the men who had already gone into the service. Allentown was somewhat different from the other camps in the country in that it had been officered by the Medical Reserve Corps and was practically not a part of the United States Army until recently. The object of the work there was to train men for the ambulance service, and this work had now been taken over by the United States Government. It had seemed that early in the summer medical men were not awake to the needs of the country, but now they were coming in very rapidly. The Southern States had given a much larger quota of men than the Northern States. Dr. Toms said that at the meeting at the Waldorf-Astoria the preceding night he had been much elated to hear that there were now 21,000 doctors enlisted and that over 14,000 had accepted commissions. Many men were doing things they had never done before. As an example of this, he said that he had been assigned to duty as a sanitary officer, and had had to assist in planning for the disposal of waste. This was no easy problem, for the camp was very much overcrowded early in the summer and the ground was a hard clay soil with absolutely no drainage, so that latrines had to be filled in frequently and new ones constructed. When they were required to have one seat for every ten men it might be imagined that this had been no small task. It was into such work that the civilian doctors had gone, but they had gone in with heart and soul, working untiringly, often holding meetings at which they discussed plans until midnight. Another interesting thing was that they had had practically no sickness in the camp. They had had no epidemic whatever, only a few cases of mumps. The Surgeon General had inspected the camp about a month ago and was highly pleased with the conditions. They had had fewer flies about the latrines than about the mess hall; this because they had been unable to screen the mess hall. Dr. Toms, in closing, said he thought that, all things taken into consideration, the doctors were waking up and coming to the front nobly, and one point worthy of note was that the best work was being done by the older men. It was remarkable the way in which the older men had grasped the situations and fitted themselves into the work. If a man of mature years was found to be a misfit, he was immediately sent off to some training camp to get the training and discipline he needed. It was to be hoped that all the men who came into the service would come in with the same spirit and determination to meet whatever situations arose and with a willingness to make any sacrifice, and then we should have what they had had in England, another illustration of the wonderful results that could be achieved through the cooperative efforts of the medical profession.

Lessons Taught in the Present War in the Treatment of Gunshot Wounds.—Dr. WALTON MARTIN of New York spoke on this subject. He said that from the discussions he had listened to at the Clinical Congress of Surgeons there were certain definite lessons in regard to war surgery that might well be emphasized. In the first place one had to take into consideration the kind of weapon that had caused the injury, whether by fragments of shrapnel, by bullets at close range, or by bullets at long range. A bullet at a range of 400 meters had a tendency to pass through the tissues and cause very little damage or contusion. The wounds in the Boer and Russian-Japanese wars were to a larger extent of this nature, and consequently the deductions drawn from experience in that war were not applicable in the present war when so many of the wounds were caused by shrapnel. The pieces of shrapnel did not

cause the clean-cut wounds such as the bullets caused, but on the other hand caused considerable contusion, did not pass through the tissues, but were apt to carry pieces of clothing or other foreign material with them and to lodge in the tissues. From an exploding shrapnel one got every kind of injury, and sometimes one man received a great number of wounds. The shrapnel caused great damage to the tissues so that there was a deposit of tissue detritus as well as the introduction of foreign material to contend with. Again a shell might strike a building, tearing it to pieces, and the flying debris might cause numerous wounds. Splinters from such a source had been known to cause numerous wounds and had been found lodged in the pericardium, the transverse colon, and other viscera of the victim. If a rifle bullet became deflected it might act like an artillery missile and damage a great area of tissue. Another point to bear in mind was that when particles of clothing and other foreign bodies had been carried into a wound surface sterilization was of no value. Frequently one got no idea from the size of the skin wound of the amount of contusion and damage lying deeper. Earlier in the war the treatment of wounds was much more conservative than it was today. Bacteriological studies had shown that the terrain of European battlefields was saturated with germs that caused infection—the Welch bacillus, streptococci, and staphylococci—and the uniforms of the soldiers became covered with this earth, and if a particle of clothing was carried into the wound it carried infection. Bacteriological studies also had shown that one did not find infecting bacilli in the wounds until eight or nine hours after the latter had been received. A few organisms would result twelve to twenty-four hours afterward in millions of descendants, so it became very evident that the main point in the treatment of these wounds was the early removal of foreign material and infected tissue. It was not sufficient merely to take out the foreign body, but one must remove all macerated tissues and all tissues that would be likely to become necrotic and serve as a culture medium for bacteria. Therefore the wound should be laid wide open and all necrotic tissue removed as well as all debris, particles of clothing, etc. This was what Dr. Carrel characterized as the mechanical treatment of the wound. He had advised that two millimeters of tissue be removed along the entire tract of the wound and that one should not respect nerves or blood vessels. The speaker, however, did not believe one should hold to such a hard and fast rule as that, owing to the fact that the amount of tissue damaged along the tract of a wound varied greatly in different wounds. Another point was that one must not think first, as had been the custom in civil practice, of repairing the damage, but must first think of getting rid of all infection. That meant a wide exicision and a great deal of operative work. It meant that surgeons of wide experience were required, and it meant *x*-ray and bacteriological examinations. It meant that a very complicated staff was needed for the treatment of war wounds. Another thing that made the treatment of war wounds a different matter from that of wounds in civil life was that the soldier had to be moved so often and treated by so many different surgeons. Dr. De Page had been on the Belgian front since the beginning of the war and had probably the model hospital of Europe. He had the management of both the base hospital and the advance hospital, which furnished conditions somewhat different and more advantageous than those found elsewhere, in that they were able to follow a wound from the start to the finish. This had contributed greatly to the good results they had obtained, for they were able to get the wounded men early and to carry out a definite plan of treatment. Another factor that complicated war surgery was that they had not one emergency case at a time but sometimes hundreds at once, so that it was not possible to give them adequate care. One point of interest was with reference to wounds of the knee. In Dr. De Page's hospital they had carried out the Carrel method in the treatment of these wounds, and they found that they had 40 per cent. of recoveries with function and only 15 per cent. amputations. They then tried simply washing out the knee wounds with Dakin's solution and closing them. With this method they had 80 per cent. of recoveries with function and no amputations. Dr. De Page reported that he got better results with the Carrel treatment in complicated fractures than with other methods of treatment. It seemed that the Carrel method was still under consideration In some wounds one obtained better results by keeping the wound open, but this was not the case in wounds of the knee

(*To be concluded.*)

PATRIOTIC RALLY AND RECEPTION UNDER THE AUSPICES OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, THE PHILADELPHIA ACADEMY OF SURGERY, THE MEDICAL CLUB OF PHILADELPHIA, AND THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

GUESTS OF HONOR: SIR BERKELEY MOYNIHAN, COL. T. H. GOODWIN, MAJOR GEORGE W. CRILE, MAJOR FRANKLIN H. MARTIN.

Held at the Bellevue-Stratford, Philadelphia.

Nov. 7, 1917.

MAJOR JOHN B. DEAVER, PRESIDING.

COL. T. H. GOODWIN, D.F.L. of the British Army in opening his address said that his instructions upon coming out to this country had been to tell the people of the United States of the mistakes—many and serious—which had been made in Great Britain in order that similar pitfalls might be avoided. One of the most serious of such errors had been the failure to realize the probable duration and severity of the present war. Recalling the astonishment and incredulity with which the British public received Lord Kitchener's statement that the war would last, at least, for three years, he emphasized that Lord Kitchener had said it would last for three years, not that it would be over in three years. He recognized the difficulty of appreciating at an area far removed from the war area conditions and necessities arising, such as the need of training the medical profession and providing a large reserve in this and other professions, the necessity for economy, conservation of fuel, public money, etc., avoidance of any wastage. To avoid distress these must be practised. The many trials and difficulties experienced by Great Britain he ventured to suggest that America would also experience. An enormous expansion would have to take place in our army and concurrently in the medical force.

An army of many thousands would be needed and in addition to the personnel of the initial army many reinforcements must be provided to replace men tired and ill and to provide against the general wastage of war. He earnestly urged that there be avoided the cardinal mistake of underestimating the enemy. "Do not believe any stories you hear as to the enemy being broken, as to its being at the end of its resources, as to the morale of the German soldier being a thing of the past," he warned, declaring that the German soldier is a brave, hard fighting, determined man, essentially patriotic, and splendidly disciplined. Illustrative of the confidence of the German soldier, officer and, presumably, of the German nation, Colonel Goodwin related his conversation with one of the German officers who had said, "Of course, America is coming into the war. We shall attend to that. We shall take steps to bring her in. We have got to pay our war cost with American money. You may laugh now, but, mark my words, you will see our victorious armies marching through the United States. We intend to teach them, as we have taught other countries, what war means. Wait and see." Such, Colonel Goodwin said, was this man's absolute belief. While Colonel Goodwin had waited and was still waiting, it was not with any confident expectation of seeing the German army in the United States that he had come out. In his opinion no civilized nation had ever imagined the utter depravity to which modern warfare could bring a nation. In reference to the "English speaking soldier" so closely had Colonel Goodwin been associated with the men of the United States Army that he thought of the officers and men exactly as of his own; he would not wish it to be otherwise. Having seen as he had the enormous amount

of suffering, pain, misery, loss, wastage, much of which might have been avoided by more forethought, more realization, more preparation, he begged that America would prepare now and leave no stone unturned to insure adequate preparation. Brief mention was made of the attention given a man shot at the front line trench. Incidentally, Colonel Goodwin observed that "up at the front" the atmosphere was not depressing, that while sometimes it was difficult to keep cheerful, the principle maintained was that one must keep cheery. Supposing that a high explosive shell did strike a regiment occupying a front line trench much less damage was done than would be thought. When one of the men was struck in the shoulder a few vitriolic remarks were heard regarding German shells, the man used his first aid dressing and a telephone message announced that he was being sent to the casualty station. Private Atkins received a dose of antitetanic serum, his arm was placed in a sling, he was put on a stretcher and sent farther back to the station of the motor ambulances and thence to the dressing station a couple of miles back. There he was given a hot meal, his wound more carefully attended to than was possible at the first aid treatment. If the wound proved more serious than at first thought the man was sent to the hospital at the base, treated there for a few weeks, and then sent to England or kept at the base hospital, perhaps being placed in the ambulance corps and later returned to the firing line. One of the cheeriest men was one who had received his ninth wound and was going back to receive his tenth. In a tribute to the British soldier Colonel Goodwin observed that he was an extremely cheerful individual; that he had known him for the best part of twenty-five years, at every sort of work and of play; in peace time and in war; in sickness and in health; under every possible condition, but had never seen him depressed. He had never seen him realize that he was beaten. The British soldier had no idea except of winning—he was either then winning, or going to tomorrow. He was the cheeriest man in the world! The same would be found true of the men of the American Army. In conversation recently with a lady Colonel Goodwin had been asked whether he hated the Germans, the hope being expressed that he did not. He replied that "hate" to him was rather a childish word; that his feeling rather was one of utter detestation and horror of German methods and system generally which were utterly opposed to all our ideas and principles. To the hope that after the war was over he was going to "forgive and forget," he had replied, "No, I am not; it would be impossible." An incident showing the spirit of the British soldier was that of two men in the hospital, each with a broken thigh. They were of different regiments and had never seen each other before, but had struck up a tremendous friendship. Both were Englishmen, both married men with families. One morning when a convoy was being sent across the Channel word came at the last moment that one more patient could be taken. On saying to these men, "I can send one of you this morning," both looked across the Channel, where there was a clear sea; both had been looking forward to this moment. Then one said, "Well, I am not feeling quite so well this morning; I don't think I will go." The other fellow said, "If you don't mind, I would rather go another time." After waiting three or four days for another boat the two men were sent off together, on cots alongside of each other. Schoolboys returning from their sports had never shown greater spirits than these two men. That boat, with sixty-three patients whom Colonel Goodwin had been looking after for weeks, was sunk by a submarine. "Personally," Colonel Goodwin said, "I don't feel at the present time like forgiving." One thing further, he would say, "I don't want to be pessimistic. I don't think of but one end, absolutely one end only, and that is a victorious end for us. But I honestly believe that a lot of water will run under the bridge, and that much hard and unremitting work has to be done before we shall attain that end. I would beg you to expect, and to prepare for a long and strenuous war. The more finished, the more unremitting your preparation, the greater and steadier your purpose, the more quickly will the war come to a satisfactory termination."

Major Franklin H. Martin, who was introduced as the representative of medicine in the Council of National Defense, expressed his sense of responsibility in his position. He characterized the war as not a little war, but rather one of a thousand years, the privilege of having part in which should fill a man's soul full. The problems involved were almost overwhelming. "Do you realize," he asked, "that the medical department of a modern army is really the backbone of that army; that our forces could not remain in Europe for one month were they not efficiently looked after by the medical department; that the problem is different from that of a hundred years ago?" Because of these things the responsibility was regarded as large. Until all of the medical profession within military age and physically fit were enrolled in one department of the service would all be accomplished which should be accomplished by the medical profession. He inquired whether there could be any one present so detached from the problem of the war that they could feel no responsibility; and if so, what explanation could they make five or ten years hence of their position. He asked whether it was realized that our enemy today is far stronger than at the beginning of the war; that she has practically doubled her territory; that the Imperial Bank of Germany holds double the amount of gold that it did the day the war began; that Germany has rolled up one country after another, organized it and then sold the products back to the country for gold, buying what she had to buy with paper; that the work of Germany was being done by her prisoners for a pittance a day; that Germany is now accumulating the indemnity she would later have to pay to these very countries she has conquered? While that was a wise provision, the speaker gave ardent thanks that England would be in at the end when the bargain was made and, with the Allies, would see that the gold is returned and that Germany paid back, not only the money taken, but she made a real recompense so far as that was possible. Speaking more especially to his subject, the Medical Department of the Council of National Defense, Major Martin said that the United States on April 6 had a standing army of medical officers to the number of 550 with 400 in the navy, that today there were enrolled in the Medical Officers' Reserve Corps 21,000 civilian doctors for work in the national army of America. With the original corps of the army there had been enrolled and accepted enough medical officers to supply an army of 2,500,000. This number, however, would not be sufficiently large, believing as he did that toward the close of the war there must be from five to six million men in the field, necessitating that there be five or six times as many medical men as at present enrolled. The medical department of the army, he said, had expanded 100 per cent. every two weeks since the war began. Attention was called to the "providential" condition existing in the surgeon general's office at the beginning of the war. At the head was General Gorgas who for thirty years had been working on a problem much larger even than the present one. With him were the men who assisted him in putting yellow fever and malaria "out of business"; there was Grayson who had made his reputation working in the navy; Braisted who had endeavored to eliminate alcohol from the navy; Blue who had eradicated the plague from San Francisco and did that great work in New Orleans. With these men at the head of the three great medical departments of the army Dr. Martin thought there was little cause for worrying concerning the outcome of the war so far as medicine is concerned. The English, he said, were taking care of their soldiers with only two and a half to three medical men to the thousand instead of the seven provided by the United States. They have been working sixteen hours a day, while we have been sitting here wondering whether we might do something. So many medical men could be sent to England, France and Italy—and the people at home would be so much better off! "Therefore, gentlemen," Major Martin exclaimed, "let us get into uniform and not have to explain in five years or twenty why we did not have a part in this great war!"

Major George W. Crile, introduced by Major Deaver as the one who had made the way to the operating table one of the rosiest paths of life, said he felt very much as though he were occupying a hole in No Man's Land, between the eloquent, patriotic speakers and the gentleman who had introduced him. Speaking, as he had

been asked to do, of the daily routine of the Americans who had gone over to do their bit, Dr. Crile described his visit to one of the casualty clearing stations, and said he had found the hospital in a tremendous turmoil of activity, men were operating with great rapidity, and by the aid of artificial light. At one end of the operating theater where things were most active, having a curiosity to know who was doing this stirring work at midnight, he had found "Dick" Harte at work. He thougnt that Philadelphia might justly be proud of the work her surgeons were doing in France. The medical man going to France, he said, would be splendidly received, located in an advantageous position, and given the preference on all sides by his colleagues. While there would be opportunity to study problems of military surgery from great masters, there had been a wonderful development in the younger men of about thirty years of age who had been operating in twelve hour shifts for two and three years, and this work they continued untiringly. Nor could he too deeply express his admiration for that greatest of all of the English medical men, Sir Alfred Keogh, who thought and talked and planned in terms of empires. Anything which he did or said would be of the greatest value. At the casualty station in France the real work of surgery is done, and incredible as it might seem the farther toward the front one went the greater "peace and harmony" were felt. With everyone thinking and working in the most single-minded way toward the achievement of one end, almost a "heavenly peace" was found at the front. Among the features of interest at the front was the bombing of hospitals. The hospital which Dr. Crile had had the honor to serve had been in existence for three years and its location was known to the Germans as proven by the map of a pilot shot down. In two nights over 200 people had been killed and wounded. Of the living conditions at the front, the British rations were excellent; though the weather was always chilly, damp, and cold the men always thrive. Apparently there is something in the atmosphere which invigorates. It was explained that in the front area very little surgery is done, good surgery not being possible until one got behind the eight mile limit of the German guns; not infrequently one wore a steel helmet when operating. It was said that at the time of the bombing of the hospitals the German prisoners were the only ones who were alarmed, and when they were told their own airplanes were bombing the hospital they cursed their own people as only Germans can curse and hate. The British soldier, Major Crile said, he had come to know better and for the Tommy had to say that he really did not know the meaning of defeat. One might leave him in Flanders and go away for a week; on coming back he would be there—living or dead—he would be there. The Tommy he designated as a good, clean fighter, in a sportsman-like way reflecting the great sense of fairness found everywhere among the British people. He had never seen among the British soldiers boasting, nor expression of hate or fear. He had seen officers only of the high type English gentleman attacking this very bad business of war with all its grimness as would a good clean sport, and the men reflected the soul of their officers. While not able to tell what would happen in this war, believing, however, that the end would be victory for the Allies, this he knew: That the British might die in Flanders, but that they never would go back to England, only and excepting after victory. So far as he was concerned Major Crile confessed to more fear in regard to the organized intelligence of Germany than in regard to her soldiers. He expressed the earnest hope that the United States in this crisis would see to it that all the intelligence she possessed was linked closely with the national defense now and for all time. He believed that her universities ought to be, in peace time and in war, a part of her national defense; in all medical schools there should be an organization of physicians, clinicians, surgeons, laboratory men, feeling a national responsibility ready to cope with the hard materialistic philosophy of the Germans. He believed that following the war all Americans would think along national lines and not settle back content with merely local interests. Such organization, he said, was now being formulated by the Council of National Defense, which he hoped would be carried to a successful issue. His observation led him to the belief that we would not realize that we are in the war until our Arlington is transferred to the foe.

Sir BERKELEY MOYNIHAN of Leeds, England, prefaced his remarks by his expression of pleasure in speaking in Philadelphia. Many years ago in the days of his "tender and callow surgical infancy" a visitor from Philadelphia had come by chance to see him operate in Leeds. This visitor had returned to Philadelphia and so arranged matters that in the following year Sir Berkeley had been invited to speak before the American Surgical Association. From this experience had come a vivifying impulse, a refreshing stimulus, which had carried him on his way ever since. He desired, therefore, to say that ever since those rather far off days he had remembered in deepest affection the memory of his well beloved friend, Dr. William L. Rodman.

The question presented and to which he desired to submit an answer was, "Why are we at war?" He observed that in the history of all wars the real underlying moral principles of war were not in the earliest days of the conflict recognized. Only the men who stood a little aloof—civilians, officials, men of letters—were the ones who revealed to the nation the real, secret underlying the tragedy being enacted. The present war, in many respects, if not in all, Sir Berkeley characterized as different from any war waged in the history of the world. An important difference was that for the first time in history there is a league of free peoples willingly fighting war together, a league of peoples who could not be coerced by any government or compelled by any autocracy to take up arms. "You, we, and we together are the only ones fighting in this war who have nothing to gain, except an addition to our already heavy responsibilities. We are fighting a war of rescue. We are fighting a war for peace."

Inquiring deeply for the cause of the war there would be found two conflicting moral systems. Prussia, the instigator of the present war, had at first a poor and infertile country. A life of self-discipline was necessary to existence. It was not long before her people recognized that in order to increase their resources they had only to exercise their powers against their nearest neighbor. Since that time Prussia had recognized one gospel only—the gospel of plunder. War is, he said, the natural industry of Prussia. It is by war that she has added to her own infertile territory; by war she has gained power and possession, and endeavored to make her people wealthy and contented. From the time when in 1864 Prussia waged her first large war she revealed to us and to the world at large a most magnificent cohesion among her own people that they might be used as a weapon in conquest of other rich and neighboring territories. Prussia made a religion of valor. While this Sir Berkeley observed might lead to the belief that the underlying cause of the war is Germany's ambition for further conquest, such answer Germany did not herself give. Germany tells you she is fighting a war of defense, that she feared there had been raised up around her frontier an impenetrable barrier of armed forces comprised of people who were jealous of her vast commercial increase and her supremacy in the business activities of the world. Not for a moment is Germany to be believed when she tells us that this is a war of defense. Were that the true answer, the truth underlying the war would be German fear. Fear is the black godmother of cruelty. Both these views, in the view of the speaker, are wrong, his opinion being that this is a war, not waged on one side or the other for merely military ends. It is a moral war. It is a holy war if there ever has been one in the world. If it is a war of moral basic principles it must be recognized that there can never be any compromise. "You cannot compromise with a principle of evil. You cannot make peace with the devil." The principle which has inspired and animated Germany in all this ghastly business through which the world is now going, and in all her ancient history, Sir Berkeley ventured to describe as the principle of tyranny. Asked to give a definition of tyranny, he would say that it is the surrender by an individual of what is best in himself to a power lying outside himself owning no allegiance from him, but directing all his purposes in conformity with its own will and purpose. It is autocracy. It is the supremacy of the State carried to its ultimate defi-

nition. That might is right is the law by which it lives.

Over against this definition of tyranny the one word which in truth could be used was "Liberty"—the indestructible right of every individual to be himself, to develop himself, to express himself, to grow from within. The difference intellectually and morally between the gospel of tyranny and the gospel of liberty in Sir Berkeley's view is that tyranny desires to stamp the intelligence of every citizen with a certain mark that he may be put into the intellectual currency of the State. Tyranny desires to so train and use an individual that he shall be of use primarily to the State. Liberty, on the other hand, desires to allow to each individual self expression and freedom of development of his own character. Freedom, he declared, can be exercised by many people together when each individual is willing and able to make some surrender of a part of himself to the State. We recognize a democracy which thrives on a liberty as a government made by ourselves. Sir Berkeley thought we do not care whether the laws are good laws; we do require that they shall be made by ourselves. In this war, therefore, were evident the conflicting systems—tyranny and liberty, autocracy and democracy; control and repression from without, growth from within. Sir Berkeley expressed his deep persuasion that for the people and for the world of science there exists an issue as critical and as grave as any that the world has before known. Tyranny uncontrolled, he showed, must mean restriction of the intellectual output, atrophy from long disuse, the negation of scientific processes, intellectual sterility and death. How impossible for a nation held in the fear of tyranny to give its citizens intellectual freedom! Progress in science must first and last depend upon unrestricted exercise of all the faculties of the mind, and of these imagination was declared to be the chief. Beneath a system of tyranny intellectual freedom could not exist; the two are absolutely incompatible. The best illustration of this Sir Berkeley believed was given by the history of Germany herself in the last forty years, for while Germany has been the intellectual clearing house of the world, her original scientific contributions in every branch of science are almost negligible. Therefore, for the fuller development of science, conquest of this spirit of German tyranny was necessary. This the speaker believed to be the philosophical explanation of the war.

Speaking of those living in England at the time of the outbreak of the war Sir Berkeley said that the National conscience had been stirred to the depths as never before. The ideals for which England had lived and fought seemed to Germany of no account. A nation's pledged word Germany had thought but "a mere scrap of paper" which conspicuous phrase would be handed down to her posterity. England stood and still stood, he said, for the rights of small nations which had been absolutely denied when Germany entered Belgium. Before the war there had been some uncertainty felt in England regarding what the colonies would do were the mother country drawn into the war. The answer he said had been amply given. Nothing, he said, could have exceeded the haste, the gallantry each had shown standing side by side to help. Instantly, upon the outbreak of the war the troubled waters of their national life were stilled, all corrupting influences sank to the bottom and it was realized that self-surrender was the best of all social antiseptics. The whole of the nation had sprung at once to arms and royalty was seen enlisting in the ranks. There had been seen as a private in the war one who was the thirteenth holder in direct succession of a Scottish earldom, and the story went, for which, however, the speaker would not vouch—that ten days from the time of being put into khaki this man was called upon to salute one who four years before had been his butler. The "salutary influence" of such an occurrence was evident. England had stood ready to do just whatever the war office required of it. Rather more than one-third of the total number of England's doctors had been given to the Army. With few exceptions, every medical man in the country under the age of forty-two, it was said, is an officer in the Royal Army Medical Corps. In Sir Berkeley's own city of Leeds, where after considerable thought they had thought they might add to their daily routine 520 military beds, they had later arranged for 6,300 beds and upon his return to England this number was to be increased to 7,200.

Of the rewards that could come to an Englishman whether or not he were wearing the uniform, as was well known, the greatest is the awarding of the Victoria Cross. Any man wearing such decoration is a marked man wherever he goes. Upon leaving England 103 such awards had been made and of that number a proportion three times as great as would be the proportion to the entire Army had been awarded in the Royal Army Medical Corps. Early in the war the first Victoria Cross was awarded to Captain Rankin of the Medical Corps who had sustained a compound fracture of the thigh, then perhaps the most serious of all possible injuries. He had been carried to a little dugout away from the front line, refusing to be taken farther away and for twenty-two hours he insisted upon dressing the wounds of the men brought to him. In that time his wound, of course, had passed from the stage of contamination to that of infection and death had occurred seven or eight days later of an acutely infected condition which had not been checked by amputation. The winning of a Victoria Cross more than twice recommended a man for a bar. Two bars had been awarded in this war, and both to doctors. Of their achievements as doctors, the greatest was considered that in connection with typhoid vaccination. If the military heroes of the war were doctors, the scientific hero was Sir Almroth Wright. In the South African war there had been 57,184 typhoid cases with 8,000 deaths. In the present war with an army ten times as large, on a soil much more likely to carry contamination with every kind of unhygienic and unsanitary difficulty, in 6,032 typhoid cases there had been but 292 deaths. If, however, science has had its victories, it has also had its disasters, it being no exaggeration to say that but for this system of typhoid inoculation the war would have been over long ago since typhoid would have destroyed both armies, the Boche and their own. In other directions also efforts had been made to solve the carrier problem and in surgery considerable advance had been made. In the beginning of the war the surgical problems presented were of a kind not before seen; by degrees, however, and by the placing of the right man in the right place —not always an easy thing to do—considerable progress had been made in the treatment of surgical conditions. In the surgery of the lung operations had been done, very different from anything that had ever been done before. One felt, Sir Berkeley said, almost as if they had had a misspent youth and a wasted career and that they should have started and remained above the diaphragm.

The story of what was for the British Army the most critical moment in the whole of the campaign in France, and in the opinion of those who knew, the most glorious achievement of the British Army, the second battle of Ypres, November 11, 1914, Sir Berkeley said had been told before, but he felt that those who had heard it would forgive his telling it again. The British Army at that time had not quite been defeated—it had suffered considerable disorganization. On November 7, the line consisted of men stretching from a tiny remnant of the Belgian Army to the French Army on the right. No man was able to touch his neighbor. In that line had been put every man at their disposal. From the Red Cross, the Y. M. C. A., any one who could hold a gun, men in the highest official positions had been placed in the line. Behind that line there was nothing of any kind whatever in reserve—not one man, not one gun, not one round of ammunition. To the men who occupied that line every available cartridge in France had been served—150 rounds apiece. There were a few machine guns, probably three or four to a battalion; they were rather poorly supplied with ammunition. From November 7 until the morning of November 11 the enemy had tried to wear out the spirits of the men by preventing them from sleeping. Those who walked along the line on November 10 reported that the men were excessively weary and dirty beyond recognition, with mud over their faces, hands and clothes. They were sodden over the ankles, the knees, the waist by the mud and water of the trenches. As the inspector passed along the line the men stiffened

for a moment, then would fall off to sleep. On the morning of November 11 the attack was made by troops that were fresh and in overwhelming numbers, never less than five to one, and at times seventeen to one. The second line of attack was made by the Prussian guard. Sir Berkeley had had under his care some of the Prussian guard after the attack. They told him that the Kaiser himself had placed men before the British line and told them on the morning to cover themselves with glory by marching through to the coast. In the early morning of November 11 the attack had come—wave after wave against weary, sleepy-eyed, uncomfortable, but cheerful Tommies who could hardly open their eyes to see what was happening in front of them, with the result that they did not hit anything until it came within about 30 or 40 yards. Over that 30 or 40 yards distance there walked next day, an officer counting the dead in heaps of eight, nine, ten and eleven! The attack had failed!! That weary, thin line was all that had stood at that moment between civilization and barbarism. And, if the Germans had known, on November 12 they might have laid down their arms and walked to the coast without anybody to stop them.

As Colonel Goodwin had already said, the conspicuous, outstanding merit of Thomas Atkins is that he is the most cheery, indomitable fellow on the face of the earth. When Sir Berkeley had made his report to Sir Douglas Haig he had ventured to say that he commanded an Army that smiled, and this smile, he said further, never wears off. With the man in the hospital, whatever his wound, he is still uncomplaining. Two kinds of courage are seen in the British soldiers—and which would be seen also in the American—physical and moral, and of the two it was hard to decide which he admired the more. The physical, perhaps anyone could understand, for in the glitter and glamor and the glory of a concerted attack, it is not difficult to be brave. In the visit, however, to the soldier at night, one could not but be touched of his awful loneliness and solitude and the aching misery of the early hours of the day. But never was there a whimper or a whisper of regret or surrender. Never would he forget one boy who had had a bad compound fracture of the knee joint which every effort had been made to save. In spite of the efforts gangrene had come on and amputation was necessary. By blood transfusion, the use of which in surgery was due to Major Crile, the boy had been put into something like fair condition. Though still a grave surgical risk the boy had had to have his chance. Sir Berkeley had seen him several times during the evening and again at half past eleven, when he had said, "Well, how are you?" Never would he forget how the boy turned his white, weary face to him and said, as loudly as he could, "I am tip-top, sir"; and at midnight he was dead.

When America joined the war it was felt in England that the conflict had taken on a different complexion altogether. America would learn, as England had learned, some of the jealousies of blood and iron. It was useless to deny that Germany is a great enemy. If, however, she had only fought clean, respect could have been felt for her. But, she is an intractable enemy, ruthless, bitter, and, as Tommy says, a "dirty fighter." It was interesting, it was stated, to hear the men talk who had fought on the different fronts. Never would the Tommy be heard to express any personal admiration for the individual Boche. As man to man Tommy held him in contempt. Never, however, would you hear a Tommy who had fought out in the East say anything derogatory to the Turk. He would tell you, rather, that the Turk is a gentleman, that he fights clean, and that it is a joy to be in arms against him. There, Sir Berkeley, expressed the hope that any who had not already done so would read John Masefield's "Gallipoli." It would be one of the imperishable memories to have read this book. Many of the boys fighting at Gallipoli had said that when a machine gun had been placed next to a hospital a polite message would be received from the Turk requesting its removal. Against the Boche, America would find that she must make long, arduous, and intense preparation; that she must expect immense losses. In America there would be many broken hearts; in the end, however, she would realize that it was worth while.

A statesman had said that only those are fit to enjoy liberty who have fought and struggled for it. Many of his friends in America, the speaker said, had asked him when the war would end, how soon Germany would be beaten. Might he say most seriously, that for Americans and for all, the answer would be given when every man of military age was ready to offer his services and to surrender his life on the high altar of patriotism where his country had laid herself, her soul, her honor; when she had borne her illustrious dead in thousands and knew that they had not died in vain, but to win the victory for the most righteous cause for which the sword had ever been drawn.

Asked what was to come out of this war for America and for England? Many friendships and great inspiration; the most splendid of all—that at last, America and England stand side by side. Could he have one prayer certainly answered it should be that nothing should ever tear them apart. Together they were civilization's largest hope. Seeing America's splendid boys at work in the hospitals abroad, and remembering that youth is the time for surrender to ideals, Sir Berkeley knew that when this war is over, there would be in England a large number of ambassadors of affection; American and Englishmen would stand side by side forever, working with unanimous effort to attain a common purpose.

In closing Sir Berkeley said, "I should like our watchword to be 'Together.' The greatest of our statesmen of the nineteenth century, in the opinion of many Englishmen, has said, 'All wars are detestable, except one war—the war for liberty.' America is fighting her third great war. The first war you think was against us. We don't think so at all. We think, and we now know more clearly than ever, that it was a war against that same German tyranny that we are fighting against today. As a result of that war America gained her separation from us. In her second war she had a fight within her own household. 'A house divided against itself,' our Lord said, 'cannot stand.' You had to settle who was to govern your own country. In the third war you are fighting with us. In your first war you won freedom for America. In your second war you won freedom in America. In this war *we* will win freedom for the world."

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE THYROID GLAND IN HEALTH AND DISEASE. By ROBERT MCCARRISON. 286 Pages. Illustrated. Price, $4.00. Published by William Wood & Company, New York.

BLOOD PICTURES. An Introduction to Clinical Hæmatology. By CECIL PRICE-JONES, M.B. 91 Pages. Illustrated. Price, $2.00. Published by Wm. Wood & Company, New York.

ELEMENTS OF FIELD HYGIENE AND SANITATION. By JOSEPH H. FORD, B.S., A.M., M.D. 248 Pages. Illustrated. Price, $1.25. Published by P. Blakiston's Son & Co., Philadelphia.

TROUBLE MENTAUX DE GUERRE. By JEAN LEPINE. 203 pages. Price, 4 fr. Published by Masson et Cie., Editeurs, Paris.

ELECTRODIAGNOSTIC DE GUERRE. By A. ZIMMERN and P. PEROL. 154 Pages. Illustrated. Price 4 fr. Published by Masson et Cie., Editeurs, Paris.

BLOOD-PRESSURE, ITS CLINICAL APPLICATIONS. By GEORGE WILLIAM NORRIS, A.B., M.D. 448 Pages. Illustrated. Price, $3.50. Published by Lea & Febiger, Philadelphia and New York.

MAMMALIAN ANATOMY WITH SPECIAL REFERENCE TO THE CAT. By ALVIN DAVISON, Ph.D. Third Edition. Revised by FRANK A. STROMSTEN, D.Sc. 241 Pages. Illustrated. Price, $2.00. Published by P. Blakiston's Son & Co., Philadelphia.

Miscellany.

Passage of Alcohol into Breast Milk.—Observation and experiment alike show that alcohol is in part eliminated by breast milk, not only in women but in the goat. Aside from this general truth cases occasionally occur in which the nurslings of hard drinking women suffer from convulsions.—*Il Policlinico.*

Health of Food Handlers.—Dublin and Harris report on an intensive examination of 1748 food handlers made at the Occupational Clinic of the New York Department of Health during 1915 and 1916. This intensive study was made possible by the co-operation of the American Museum of Safety and is considered typical of the entire number of food-handlers, 44,042 examined at the clinic and 35,000 by private physicians during the same period. This group includes waiters and waitresses, male and female cooks, other kitchen employes, and bakers. Among the 1748 individuals there were 10 cases of active tuberculosis, 12 of suspected, and three of arrested, tuberculosis. Among 645 waiters, 37 gave evidence of active or suspected syphilis. This group furnished 46 individuals with flat feet and a similar number with varicose veins. Of the 211 waitresses 65.8 per cent showed anemia and 62 had varicose veins; 17.1 per cent were reported as suffering from some form of menstrual disturbance. The predominating defect among cooks was organic heart disease, there being 32 who showed evidence of cardiac disease. Of these cooks 161 had very marked disturbance of the digestive functions. Among bakers there was no tuberculosis or active syphilis but there were 33 cases of chronic bronchial conditions.

The Need of Saving Wood Ashes.—Many years ago wood ashes were the chief source of potash lye in France, as in other countries. The German potash industry obtained a world market while at about the same period coal began to replace wood as fuel. Fifty years ago wood ashes were already quite expensive and ultimately sodium carbonate came to be substituted extensively for potash lye in the arts. Now coal has become scarce and more wood must be used, the ash of which must be carefully husbanded because of its content not only of potassium carbonate but of earthy phosphates which are needed as fertilizer. Thus writes Dr. Carles in the *Gazette hebdomadaire des sciences medicales de Bordeaux* for October 14. Other useful chemical substances can be obtained from wood ashes. Much plant refuse not used as fuel can be incinerated for its ash and dead leaves are notably rich in potash. Wine growers quite ignore the fact that the prunings of the vineyards represent a veritable by-product because of their potash content. In the domestic use of potash lye the latter is habitually wasted because of the foul odor developed, although its logical destiny is the soil in which it serves as food for vegetation. Especially do growing vines require it for the potassium tartrate of the grapes. Potatoes and cereals both require plenty of potash. Sodium cannot in the least replace it. This problem especially concerns the drug market and the pharmacists should lead a movement to "save the ashes."

Therapeutic Hints.

Hemorrhoids.—Hare offers the following to be used as a suppository in this condition, if there is a tendency to slight hemorrhage:

℞ Acidi gallici.....gr. xx (1.3)
Extract. opii.....gr. j (0.06)
Extract. belladonnæ foliorum.gr. ij (0.12)
Olei theobromatis.....q.s.
Fiant suppositoriæ No. x.
Sig.—Use one every night.

In place of this, distilled witch-hazel extract may be injected into the rectum in doses of one to two ounces (30.0-60.0).

If the hemorrhoid is prolapsed and inflamed and difficult of reduction, the following ointment of Mathews may be ordered:

℞ Cocainæ .....gr. xij (0.8)
Iodoformi.....ʒ j (4.0)
Extract. opii.....gr. xxx (2.0)
Petrolati.....ʒ j (30.0).
M. Sig.—Use as a salve.

It is to be noticed that this prescription calls for cocaine, not cocaine hydrochloride. The salt of cocaine does not act well when mixed in an ointment.

If the pile still refuses to be reduced, the patient should be placed in bed and a hot compress wet with adrenalin chloride solution (1:2000) applied. If this fails, operation is indicated.

The treatment of external piles themselves calls for the utmost cleanliness. Immediately after each movement the parts should be thoroughly washed with a sponge dipped in cold water, or, by the use of a bidet or a nozzle attached to a fountain syringe or to the general water supply. Then the distilled extract of witch-hazel should be applied. Often it is wise to precede the daily evacuation of the bowels by a rectal injection of cold water to soften the feces and to decrease congestion. If there is much inflammation the patient should be placed in bed and cold injections frequently repeated or hot compresses applied to the anus. After this a lotion of lead water and laudanum—laudanum fʒss (15.0) to dilute lead water fʒij (60.0) may be used.

If in association with the hemorrhoids there is much itching the following salve may be applied:

℞ Mentholis .....gr. xx.
Hydrargyri chloridi mitis.....gr. xxx.
Petrolati.....ʒ j (30)
M. Sig.—Apply locally.—*Practical Therapeutics.*

Alopecia Areata.—Sutton advises the use of hexamethylenamine 5 to 10 grains after each meal in plenty of water. This may be taken for several days, then discontinued, and resumed. He also employs one of Bulkley's formulæ for external application on the scalp, phenol, 95 per cent., to be applied weekly, but not more than 50 c.c. area to be covered at a time. When applied to the face, the phenol is diluted one-half with glycerin.

The following formula is also used:

℞ Hydrargyri chloridi corrosivi.....
gr. 1/6 (0.01)
Chlorali hydrati .....ʒ ij (8.0)
Spiritus acidi formici. N. F...ʒiv (15.0)
Olei ricini.....mɱ v (0.3)
Alcoholis.....q.s. ad fʒ vi (180.0)
M. et Sig.—Shake and apply at night.

THE PSYCHICAL CHANGES OBSERVED IN PULMONARY TUBERCULOSIS AND ITS RELATION TO INSANITY.

BY S. A. SILK, PH.G., M.D.,

WASHINGTON, D. C.

ASSISTANT PHYSICIAN, GOVERNMENT HOSPITAL FOR THE INSANE, WASHINGTON, D. C.; FORMERLY RESIDENT PHYSICIAN, PHILADELPHIA GENERAL HOSPITAL; ASSISTANT PHYSICIAN, PENNSYLVANIA STATE SANATORIUM FOR TUBERCULOSIS, MONT ALTO, PA.; MEDICAL SUPERINTENDENT, J. C. R. A. SANATORIUM, LOS ANGELES, CAL.

To the student of psychology it is, of course, quite evident that the sudden realization by an individual that he is suffering from a possibly fatal disease, as tuberculosis* is reputed to be, acting as a sudden, unpleasant stimulus, will necessarily produce a corresponding reaction in the individual as a whole, profoundly affecting his future behavior, compelling him to make many new adjustments and adaptations to his environment, which in time will be reflected through certain changes in the psyche—the highest level of human behavior.

The medical profession, however, until quite lately entirely neglected the psychological side of the patient. In treating a patient for any complaint, the physician was merely concerned with changes in the structure or function of individual organs, and if, after a careful examination, none could be established, the patient was told that he was not suffering from any demonstrable disease, and hence not a case for medical treatment—leaving him the choice of applying for relief to the Christian Scientist, or any other medical pretender.

With the advent of psychology as a definite science, and with the more accurate methods of clinical study of disease, the psychology of the various changes in the psyche of the patient, their influence on the progress of the disease, is vaguely becoming realized by the medical profession at large. Very little attention, however, is still being paid to the psychological side of the patient by the general practitioner.

One of the most important diseases that forced, so to speak, the medical profession to the realization of the importance of psychological phenomena in connection with disease is pulmonary tuberculosis. This has been specially so since improved methods in diagnosis and modern sanatorium treatment allowed the physician an opportunity to observe such cases during a much longer period of time than formerly, when they were recognized mostly in the advanced stages and were seen by the physician only at irregular and infrequent intervals.

It was observed that patients suffering from pulmonary tuberculosis manifest certain changes in character and mental traits, that the disease often shows marked improvement under certain changes, such as change of climate, change of physician, or even the administration of some innocuous remedy, which by itself could not have influenced the physical condition of the patient. Again the frequency or rather the apparent frequency of pulmonary tuberculosis among the so-called insane seemed to point to some relationship of pulmonary tuberculosis to the psychical functions of the individual.

The rôle of pulmonary tuberculosis in producing the above-mentioned changes, its relation to mental disease, and the influence of the various psychical changes on the progress of the disease have not as yet been satisfactorily discussed. It is the hope of the writer, who has had the opportunity of studying pulmonary tuberculosis in one of the largest sanatoria in the United States and also in one of the most modern hospitals for mental diseases—to throw some additional light on this very interesting subject.

For the sake of convenience I shall treat the subject of this paper under the two headings as it usually appears in the medical literature: (I) The Psychology of Pulmonary Tuberculosis; referring to the psychical changes observed in those suffering from pulmonary tuberculosis, but which do not lead to any definite psychoses. (II) The Relationship of Pulmonary Tuberculosis to Insanity, or Actual Psychoses.

I. The thought that the individual afflicted with pulmonary tuberculosis shows profound changes in his character and mental traits as a direct result of the disease has been frequently reflected in the general literature. The writer of fiction vividly describes various changes in the mental traits and character of his hero such as selfishness, jealousy, suspicion, lack of fixity of purpose, emotional instability, etc., and because the hero suffers or actually dies from pulmonary tuberculosis, that disease is accepted as the only cause for the above-mentioned changes, without mentioning at all any other causes such as hereditary, nervous, or neurotic disposition, without taking into consideration the environment —educational, moral and otherwise—during childhood of the hero, when the corner stone is laid for the structure known in later life as character, and disregarding other factors in the life of the hero which were responsible either partly or entirely

*Whenever tuberculosis is spoken of in this paper pulmonary tuberculosis is understood.

for the behavior of the hero as portrayed. As examples may be taken "Camille," by Dumas, and "L'Aiglon," by Rostand. Strange to say, some of the medical writers on the subject frequently use such characters as portrayed in fiction as proof that pulmonary tuberculosis is responsible for various psychical changes. Considering the great prevalence of tuberculosis, comparatively little has been written by modern phthisiologists with reference to the psychological side of the problem.

On reviewing the medical literature on the subject, one is amazed at the contradictory statements and ideas expressed by equally well-known authorities, as to the forms and causes of the psychical changes observed in sufferers from pulmonary tuberculosis. According to some writers, the changes are very few, but decided, while others mention almost every mental trait known to psychology. Some writers consider these changes to be directly due to the disease itself, while others consider them due to influences altogether outside of the disease. Some writers think that the toxemia or toxins of tuberculosis are specifically responsible for the above-mentioned changes, while others give them only a secondary place of importance as a causative agent, and still others absolutely deny their significance as an etiological factor in the production of the psychical changes observed.

De Santos Saxe,[1] who is quoted by many others, states that pulmonary tuberculosis produces such profound changes in the mental traits that it often leads to crime and insanity. Mental disturbances range from slight irritability of the nervous system to mania and melancholia. Early stages are manifested by neurasthenia, psychosthenia, hypochrondriacal and hysterical symptoms. With the progress of the disease more distinct changes take place, the main characteristics of which are, "loss of willpower and self-control, and ascendency to brute selfishness." There is also present abnormal increased susceptibility to external mental influence, variability of temper, tendency to rapid psychical fatigue, change in sexual instinct, which, according to Gerhardt, is seen in the more frequent prevalence of venereal diseases in tuberculous individuals, due to increased sexual indulgence, and last but not least, tendency to crime. The above changes are all due to the tuberculous infection.

Fishberg[2] quotes Saxe, but his list is somewhat shorter; he states that "Beginning phthisis finds expression (often before physical signs are demonstrable) in changes in character and exaggerated tendency to emotional disorders. They are absorbed in themselves, note the minutest changes in their symptoms, hardly speak of anything else, are optimistic." He specially emphasizes great selfishness, disregard for others, and sexual eroticism.

Kiernan[3] and Alexander,[4] in different papers, speak of the poet Keats' life, and emphasize such mental traits as irascibility, irritability, and great suspicion as all due to pulmonary tuberculosis.

Maudsley (quoted by Clouston[15]) states that persons of a strongly tuberculous diathesis and with a consumptive heredity exhibit a phthisical psychology—irregular mental brilliancy without balance, incapacity for continued mental exertion, a causeless change from hope to despair, a causeless suspicion at times. Tuberculous individuals show whimsical notions, mental unrest, vivid fancies almost amounting to delusions.

Brock[5] thinks the chief mental trait is neurasthenia; the nervous system is out of gear, due less to the physical condition than to the general moral environment—that they are being shunned by everybody.

Milton[6] thinks that the only characteristic mental symptom in pulmonary tuberculosis is the black despair common to the first stages.

Letule[7] thinks that in the early stages the intellectual aptitudes are sharpened in a singular way. Memory, judgment, finesse in reasoning, critical sense, all these mental reactions are placed in evidence in contrast to the physical forces which remain stationary and shortly decrease. As the disease advances mental peculiarities undergo changes. Brain work is performed by fits and starts, there is overexcitability. Moral defects of the consumptive, whether hereditary or acquired, are exaggerated, never alienated. Sadness is imprinted. The predominant feature is egoism. He does not think that the mental traits *per se* change, but the patient simply shows himself in his true color. The "toxemia" robs him of the sense of proportion. In his instinctive desire to live he cuts loose from all ethical and conventional precepts.

According to Gubb,[8] tuberculosis produces intensification of cerebral functions according to temperament. Under its influence the artistic and imaginative faculties are often stimulated. He quotes Mauclair, "who instances Watteau and a number of other great men, as Schubert, Chopin, Verlaine, Heine, Mozart, and others who died of pulmonary tuberculosis, in whom the tuberculous infection seemed to have developed their faculties to a previously unattained brilliancy." He concludes by saying that the physiological influence of phthisis merely accentuates the natural predisposition to idealism.

Carncross,[9] who attempted to study this question in a scientific and statistical way in the dispensary and hospital of the Henry Phipps Institute, believes that the psychological changes are due to chronic illness rather than to tuberculosis specifically. Definite morbid psychological states usually occur in the later stages; the patients are morose, very irritable, quick to suspect, ready to find fault, perverse, antagonistic, almost abusive, skeptical, open to suggestion temporarily. Only the above, however, are observed in individuals who are self-willed rather than cheerful, good natured, and of yielding temper.

Guy A. Fitzgerald[10] states there are no changes in the mental or emotional characteristics in patients during the pretuberculous or initial stages. He states that tuberculosis is more apt to attack the weak, nervous and degenerate types, who often have an hereditary predisposition to insanity or nervous disease, and these will often show changes in the emotional and intellectual fields, but these changes are certainly not due to tuberculosis or its toxins. The ranks of the tuberculous among the better classes are recruited mostly from the hard-working, ambitious, nervous element, among whom are found the keenest minds and brightest intellects, in whom no sign of emotional or mental aberration can be dem-

onstrated. According to him it is a fallacy to regard the tuberculous as selfish and unmindful of the comforts of others (this may be observed at times in the last stages), but various peculiarities may have existed before the disease and passed unnoticed.

He states that the loss of will-power and self-control emphasized by some writers is noted late in the disease—the true character comes to the surface, but it is not due to the disease or its toxins acting on the nervous system, rather to the throwing down of barriers and to the failure of the person to restrain himself as he has no longer any special goal and is indifferent to social opinion. He disagrees with the other writers that the tuberculous patient is optimistic or shows impulsiveness, deficient energy for work, vacillation or obstinacy, or that he is more irritable, emotional, or excitable. According to him the sufferer from tuberculosis is as brave, unselfish, and devoted to high ideals as the average man. He quotes Dr. Knopf and his report of the action of the patients at North Brothers Island during the Slocum disaster. Sick patients rushing into the water and working side by side with attendants to save lives. Depression and melancholia are due to the attitude of the healthy friends who shun and avoid him, and the timidity and desire to avoid society are due to consideration for others and the dislike of pity and not to pathological causes.

Burr[11] thinks that the hyperexcitability in early stages persists in latent cases during life and may be accountable for a heightened mentality. He mentions the life of Robert Louis Stevenson, who was free from any pathological tendencies and whose cheerfulness and unselfishness persisted to the last minute. He does not think that the tuberculous patient is especially selfish or egotistical. Selfishness, egoism, and vicious tendencies are common to a large portion of humanity. He relates the following interesting story of a soldier, pointing the unselfishness of the tuberculous individual:

"A soldier upon discovering that he had tuberculosis shut himself up in his tent, paralyzed by the dread realization of his condition. He then asked his captain to release him because of disability, but the latter roughly told him a bullet would be the best remedy for him. A few days later he saved a woman's life by carrying her out from a burning building at the risk of his own life. Shortly after he risked his life to save those of his comrades by carrying away a burning bomb thrown by the enemy within their entrenchments. From this time on his promotion was rapid and he became the trusted commander of a division. He was not of heroic proportions—a Death's head surmounting a bag of bones."

Burr states that though the sexual instinct is commonly accentuated in the tuberculous patient, a stronger effort is made by the subject for its regulation and suppression.

Jacobson,[12] in his article on "Tuberculosis and Genius," maintains that tuberculosis, though not creating genius and not even giving impetus to the natural spark creating genius, nevertheless acts as a quickener of the already germinating or flowering faculties of extraordinary potentiality. He quotes John Bessner Huber who, discussing the influence of tuberculosis upon literature and the arts, with special reference to the lives of Robert Louis Stevenson, Chopin, Keats and Marie Bashkirtsef, comes to the same conclusion, namely, that the quality of genius may in some cases at least be influenced by tuberculosis. Dr. Jacobson contrasts the relation of tuberculosis to genius with that of insanity to genius. He maintains that the latter is "antithetic" to the faculties that actuate the creative mind, as insanity hampers genius and the individual of an insane temperament shows in his writings the better part—the saner part—of himself. Tuberculosis, on the other hand, is "synergetic"; it helps a genius by sharpening his faculties. Trudeau (quoted by Alexander[4]), on the other hand, in writing about Robert Louis Stevenson while the latter was a patient in the Adirondack Sanatorium, shows a marring, but not a creative influence of tuberculosis on genius.

So, judging from the medical literature, the psychology of tuberculosis is by no means a settled question. Some writers deny that there is such a "species" altogether, but still more diverse are the opinions as to the forms and manners in which the psychology of the tuberculous individual expresses itself, and the causes for the same. How can we account for the fact that such an eminent authority on tuberculosis as Dr. Fishberg strongly emphasizes "egoism" as one of the chief mental traits in tuberculosis, while the equally eminent clinician and authority, Dr. Knopf, vigorously opposes the same? How can we reconcile such diametrically opposite views as ascendency to brute selfishness, throwing off barriers of civilization, and that tuberculosis tends to bring out the artistic and stimulates the predisposition to idealism? The explanation, however, is quite evident: It is due to the different viewpoints of the various authors as to what constitutes the "psychology" of an individual, and also because of difference in type and surroundings of patients observed by the various authors. It is assumed by some writers that such traits as selfishness and suspicion are something distinct from the individual as a whole—that they suddenly appear or disappear without leaving any trace. The recent studies in psychology, especially the psychoanalytic methods, have shown us that the only right way to understand the wherefore and why of the psychology of the individual and his mental traits is the "genetic approach"—which considers man at any given moment in relation not only to what has taken place since his first day of coming into the world, his "ontogenesis," but also what has gone long before him, racial and other characteristics—his "phylogenesis." Every mental trait observed in an individual has a past,[13] and is intimately connected with the individual as a whole. Viewed from this standpoint, there cannot be any question as to a special "tubercular psychology" as the thousands of individuals suffering from tuberculosis, having different phylogeneses and ontogeneses, cannot have the same psychology. The question may, however, arise whether tuberculosis or its toxins do not modify in any way the psychology of the individual, whatever it may have been before the onset of the disease, and whether certain mental traits are not exaggerated or diminished.

Before entering into a discussion of the above we must bear in mind that even "healthy" people pre-

sent great variations in mental traits, that the healthy individual may be the possessor of various traits which are either pathological or on the border line and which remain latent for a long time and only come to the surface now and then under certain conditions. The considerate and idealistic often act in the most selfish ways and the egoist shows himself to be generous and capable of self-sacrifice—the personality of the individual is quite polyvalent, many traits and characteristics are latent, others are repressed and still others come to the surface only now and then. We must also remember that the so-called neurasthenic, neurotic, psychopathic, and constitutionally inferior individuals form quite a percentage of the "healthy" community. It would, of course, be unreasonable to expect them to be immune from tuberculosis, and so when we observe certain mental traits, or individuals of certain types of personality, among the tuberculous, we must not always blame tuberculosis, unless we are convinced that these pathological traits are in far greater percentage among the tuberculous than among the average healthy individuals.

My own observations of tuberculous individuals in all stages during several years do not agree that there are definite changes in the character or mental traits of those individuals, which would be considered either separately or in groups as characteristic of this disease or existing in the majority of individuals so affected. Various changes and modifications of mental traits are observed, but these changes are in no way characteristic of tuberculosis nor can their presence give the slightest justification for suspecting an individual showing such changes to be suffering from pulmonary tuberculosis.

The realization by a person that he has pulmonary tuberculosis brings him face to face with one of the most serious difficulties he may be called upon to meet during his life. He must meet such a difficulty by many new adjustments, and must adapt himself to many new conditions and environments, and just as healthy individuals react differently though under the same difficulty, the tuberculous individual is no exception, and shows just as many reactions and different forms of adaptation to his new conditions and environment.

The loss of both legs by an individual would constitute a serious difficulty in his life, but not all individuals would be affected similarly by the same and not all would adjust or adapt themselves to the new condition in exactly the same way. The man of means, who does not have to exert himself to make a livelihood, may secure a good set of artificial limbs or have some one wheel him around in a chair, and if he is of a quiet disposition or inclined to a sedentary life may devote himself to some special study, perfect himself in a certain branch of knowledge and so become a very useful member of the community, thus securing the contentment that a life of usefulness brings, while if the same thing should happen to a young man to whom life is one round of pleasure, and who either because he lacks the right potential qualities or because of poor heredity or poor rearing, is unable to divert his energy and sublimate himself, may become despondent and attempt suicide, for to him life would not be worth living. Still another individual, of a lower cultural level, might take advantage of the pity his physical condition would create in others, and, deciding that the "world owed him a living," might try to live on the charity of the community without even attempting to make himself useful in any way whatsoever. And so we could continue showing that each individual meets the same difficulty in a different way, depending upon individual peculiarities and the force of circumstances. The tuberculous individual is no exception. The diverse views and opinions expressed by various writers regarding such a one are due to the fact that each observed different classes of people and under entirely different surroundings.

The Russian Jew, as seen on the East Side of New York, for instance, and of whom Dr. Fishberg usually speaks, who has for centuries been constantly persecuted and who has met his difficulties by shedding tears or praying to his God—who survived, not through retaliation and aggression, but rather by the power of endurance, cannot be expected to meet such a serious difficulty as tuberculosis in the same way as the average American, seen in private or state institutions, in whom the fighting spirit and the spirit of "seeing a thing through" in spite of all obstacles, is highly developed, would meet it, and this is why Guy F. Fitzgerald, who speaks of the tuberculous of the better classes, declares that among them the keenest minds and brightest intellects are found and in them no sign of mental or emotional aberration can be found.

My own observations of various classes lead me to believe that the great majority of patients show a distinct depression following the diagnosis of the disease, but not any more than would be natural under such a serious situation; however, as time goes on and the disease runs a chronic course causing little discomfort, they soon make certain adjustments, become partially reconciled, modifying their lives and making plans for the future compatible with the disease. That they are too optimistic is absolutely untrue. The great majority of patients of ordinary intelligence fully realize their condition but they hope that under certain conditions they may live for many years, and this is not unreasonable in view of the hope held out by physicians.

It is about time we free ourselves from the "optimism myth" in tuberculosis, which I think has persisted, at least, in part because of the name "spes phthisica," and of which some writers seem to be so fond. In the very late stages of the tuberculous, due to beginning of dissolution, his judgment may be greatly impaired and he may fail to appreciate his condition, speaking about plans for the future when he is on his death bed, but to speak of such impaired judgment as "spes phthisica," characteristic of a tuberculous individual who may live for five, ten or many more years is erroneous, to say the least.

There is, however, a certain percentage of people who, because of poor physical development or of hereditary predisposition, have for many years unconsciously realized that they have or are predisposed to tuberculosis; the thought of the death from tuberculosis of a parent, brother, sister or other

near relative frequently has entered into their consciousness, but because of the unpleasantness such thoughts occasion they have been repressed; this repression, however, is not easily accomplished. There is always a great deal of energy lost by such an individual in trying not to allow these thoughts into his consciousness. Thus he will constantly avoid this subject. If ill, specially if suffering from a cold or cough, he will not consult a physician, though frequently thinking himself suffering from tuberculosis. When relatives or friends suggest to such an individual that he consult a physician he frequently resents it and declares most emphatically that he is in perfect health, that he merely suffers from a slight cold. As such individuals are frequently undernourished and below weight, they anticipate any possible suggestion from their friends by declaring this to be a "family trait," that nobody of their family was ever fleshy, which by itself is true, but which is really a veiled admission, a "slip of the togue," so to speak, that many of the family were subject to tuberculosis. Such individuals are under a tremendous nervous strain, the unconscious thoughts of tuberculosis and the fear of death connected with it, especially among the Russian immigrants, who regard tuberculosis as fatal within a few years, dominate their behavior; they are unable to concentrate their energy on one steady goal, they frequently change occupations, climates, etc., and often develop various obsessions or neuroses or become hypochrondriacal or neurasthenic. A most interesting case of a severe compulsion—neurosis where through a skillful psychoanalytic process the underlying cause was found to be a repressed thought of pulmonary tuberculosis is reported by Dr. Frink, in the *Psychoanalytic Review*." It certainly throws a new light and offers a different explanation for neurasthenia and the neuroses in general and as observed among the tuberculous in particular. This is very important to bear in mind as many individuals who, though having a hereditary predisposition, but in whom the disease is either absent or only present in a latent form, actually develop or hasten the development of this disease through the constant drain upon their energy which such a fear or unsuccessful effort at repression must produce, for this naturally lowers the vitality of the individual and renders him more susceptable to the disease. In such individuals the diagnosis of pulmonary tuberculosis often results in a certain degree of optimism, they feel relieved, as the criminal feels relieved after confession. The energy which they used in order to secure repression is released and they can turn it to other and more useful directions; these may be the cases of heightened mentality, the increased mental productivity reported by some writers as characteristic of tuberculosis.

There are quite a few patients who, though poorly developed and possessing a distinct tuberculous heredity, show various mental traits such as emotional instability or depression, alternating with periods of feverish activity and increased ambition, lack of fixity of purpose, etc. The worry over tuberculosis is often given as cause for the above by the patients themselves. Upon further study, however, one may find that those mental traits are due to certain difficulties, the causes of which are more deeply rooted. These difficulties usually consist of certain wishes and desires relative to sex matters which the patient developed during childhood and which, because they are tabooed by society, he tries to repress. The repression, however, is not complete, and various neurotic symptoms develop which the patient ascribes to the worry over tuberculosis. This situation becomes further complicated as the efforts at repression, acting as a constant drain upon the energy of the individual, serve to lower his vitality, often lighting up a tuberculous focus which was previously arrested or "cured," and the appearance of tuberculosis acting as an additional difficulty in the life of such an individual accentuates those mental traits which were present before. The tuberculous process in such cases is apt to be of a more progressive nature unless the patient in the meantime is helped in some way out of his original difficulties. A case somewhat illustrating the above came under my observation recently:

Case I.—J. F. S., a soldier 32 years of age, was admitted to the Government Hospital for the Insane suffering from depression and giving a history of having attempted suicide by inhaling "gas." This patient served in the army for 8 years continuously. Was out of the army about 2½ years and reenlisted for the fourth time about three months prior to his admission to this hospital. Upon admission he was depressed, worried, hypochondriacal, and nervous, was constantly biting his finger nails, and could not sit still for any length of time. He was oriented in all spheres, conversed rationally, and was free from delusions and hallucinations. He stated that he enlisted the last time while in an intoxicated condition, that he knows he has tuberculosis and has worried a great deal about it. Shortly after enlistment he went to town, began to drink, and instead of returning to his camp went home to his mother. Later on when he sobered up he tried to commit suicide because of worry over his tuberculous condition and because of his breach against military regulations. He gave a strong history of periodical indulgence in alcohol; he was court-martialed eighteen times while in the army because of alcoholic indulgence. The reason for his alcoholic indulgence he gave as "worry over tuberculosis." Patient stated he had always suspected himself of being tuberculous, because his mother's entire family, three brothers and five sisters, died of tuberculosis. His mother is in poor health and one brother is subject to tuberculosis. That whenever he would begin to worry over his physical condition he would take to drink. Upon examination of patient's chest the right upper lobe was found to be markedly infiltrated, there was beginning cavity formation at the apex, and other areas of infiltration were found over middle right lobe and left apex, the disease being moderately active. Here we have a case of neurasthenia, hypochondriasis, and alcoholism, all apparently due to the worry over tuberculosis and, some would think, to actual tuberculosis though the man began to worry and drink at 17, while he is 32 now and, leading the life he did, it is hardly probable that he would have lived 15 years had he been suffering from tuberculosis all the time. Upon further examination, however, we find a history of autoerotic sexual indulgence since 6 years of age; this was continued while in the army; he was usually drunk during such acts. Here then the patient drinks so as to be able to overcome the social and cultural taboos placed on the practice which he desires to perform. Undoubtedly these practices worried him a great deal, but instead of admitting to himself that he is worried because he is the possessor of such wishes and inclinations, he transfers that to the "worry over tuberculosis." I shall not go into further details as to other possible causes, psychological and otherwise, which influenced his behavior.

Suffice to say that this patient is neurotic from causes altogether different. His difficulties which caused the neurosis undoubtedly helped to activate

a dormant tuberculous process, if not actually start it through lowering his vitality. So that tuberculosis in such a case is not the cause of neurasthenia or other neurosis, but rather the result of it, although when tuberculosis really appears it aggravates and brings to the surface more clearly any prexisting neurosis.

In a similar way can we explain other mental traits and changes in character as observed in tuberculous individuals.

Various writers discuss the life of the poet Keats as a proof of the influence of pulmonary tuberculosis in causing changes in character and various mental traits of the individual. Keats' irascibility, lack of fixity of purpose, emotional instability, suspicion, etc., are all attributed directly to the effect of tuberculosis or the tuberculous toxemia. While these writers do not give us any details as to the poet's childhood and his surroundings during that period, they mention certain facts about his life which would indicate sufficient causes for the genesis of his various mental traits later on in life. To begin with, Keats' mother was of a neurotic disposition and almost an invalid on account of tuberculosis, from which indeed she died. We are also told that when three years of age Keats was already wilful; he locked up his mother in a room and threatened to kill her if she left it. Here we have a neurotic heredity and wilfulness which, at three years of age, could hardly have been due to tuberculosis or its toxins. The psychologists know pretty well the causes for similar wilfulness in children where there is no trace of tuberculosis. Leaving as unsolved any possible faulty development during childhood, as in his manner of bringing up or his surroundings, which may have been the source of various difficulties of a sexual nature later on in life, the knowledge that his mother died of tuberculosis, that he remembered his mother, that he studied medicine later on in life, and if we also remember the views held at that time regarding tuberculosis we will see that the fear of tuberculosis was the great "complex" in his life which probably produced the above-mentioned mental traits and which undoubtedly favored the appearance of tuberculosis, the latter, in turn, aggravating the preexisting traits. Suspicion—mentioned as the characteristic mental trait in Keats' life and also by various other writers as the characteristic symptom of tuberculosis—is due to the fact that the individual constantly labors to suppress the thoughts that he is suffering from tuberculosis and is always suspicious lest the other person will guess his secret. Such individuals are constantly on the defensive, and the most innocent remarks as to their health or appearance make them suspicious. The young man is always apprehensive of his lady love lest she discover his secret and her least inattention or coldness makes him at once suspicious. This is the result of the unjust attitude on the part of the healthy community toward its members known to be tuberculous. They are shunned by their friends and made to feel that they are undesirable members of society. The mad fear of the disease often turns away from them their nearest and dearest. Under such circumstances their "suspicion" is nothing more than one of their weapons of self-preservation.

From what was said above, it is quite evident that the writer of these pages does not adhere to the toxemia theory as responsible for changes in the character or mental traits observed in tuberculous individuals.

The "tuberculous toxemia" theory is neither logical nor scientific. The various mental traits and changes in character supposed to be due to tuberculosis are often shown by the authors upholding the "toxemia" theory to have been manifested since childhood and to have existed a great number of years, and, while we admit that the tuberculous process often begins in childhood, and is only reactivated in later years, we certainly do not admit that there was a toxemia during all those years.

Saxe,[1] in proof of the "toxemia theory," quotes Dufour and Dide, who found that in three out of ten patients receiving tuberculin treatment, they were able to evoke headache, delirium, and other cerebral symptoms by injecting what is now considered excessive doses of tuberculin. The line of symptoms produced in these patients indicated conclusively (!) that the mental symptoms of tuberculin were toxic in origin.

If we should assume that there is a special toxemia in tuberculosis it must, of course, manifest itself by certain symptoms, such as headache, slight fever, increased pulse, etc. We know, however, that tuberculosis, which often lasts many years, shows such symptoms for only a very short time, which would indicate that in the interval there was no toxemia; then the mental traits, if caused by the toxemia, should disappear just as the fever, rapid pulse, etc., disappeared. The researches of Vaughan[16] have shown that certain body reactions known as "toxic" do not depend on any specific agent; that they are reactions on the part of the body against a foreign protein of any kind, and Crile[16] has shown that the same reactions occur when the body reacts against any injury, whether real or psychic representations of one, such as fear. This, of course, is noted clinically; the patients coming up for an examination when they are afraid that their disease is progressing frequently show a rise of temperature, rapid pulse, headache, etc., though they were free from them previously and these promptly disappear when the physician assures them that their disease is becoming arrested or cured. The toxic symptoms following injections of tuberculin—or "reactions," as they are called—are in no way different from those caused by injection of any other vaccine, and injections of water are often followed by similar reactions.

That the changes in the mental traits are not due to the disease itself, but to the new adjustments the individual is forced to make, is illustrated by cases which are discovered in the far advanced stage where the disease has progressed so slowly that the patient never suspected it, in which cases no change of mental traits were ever observed. It is known, however, that the mere fear of tuberculosis where there is no actual disease produces marked changes in the mental make-up of the individual. I venture to say that if 100 healthy individuals could be made believe that they are suffering from pulmonary tuberculosis they would show similar changes, and there would be as many variations in the mental traits as there were actual sufferers from the disease.

Carncross[9] questioned 237 patients at the Henry Phipps Institute, the majority being those coming to the dispensary for treatment, with a view of determining disposition and changes in the mental traits of those suffering from tuberculosis.

The following interesting data were obtained: 135 were of a cheerful disposition; of this number 42 became less cheerful with the advent of the disease; 22 were unhappy; 29 were intermediate; 31 not recorded; those originally pessimistic became more so.

Among the 237, 30 were non-tuberculous, 148 showed some change in disposition—18 were non-tuberculous; 58 showed no change—5 were non-tuberculous; 31 not recorded—7 non-tuberculous. The most common change was the birth and growth of irritability: 109 confessed to irritability, among them were 11 non-tuberculous.

Mental Attitude.—166 were hopeful, among them 16 were non-tuberculous; 32 not hopeful, among them 4 non-tuberculous; 1 was indifferent; 38 not recorded, 10 non-tuberculous.

Depression.—66 were depressed most of the time—among them were 6 non-tuberculous; 49 at times, among them 10 non-tuberculous; 14 seldom, 1 non-tuberculous; 71 not depressed, among them 6 non-tuberculous; 43 no record, among them 7 non-tuberculous.

Suspicion.—10 were suspicious, among them 2 non-tuberculous; 184 were not suspicious, among them 20 non-tuberculous; 43 not recorded, among them 8 non-tuberculous.

From the above we see that among non-selected tuberculous cases showing various changes in mental traits, the same were found almost in the same percentage among those who "believed themselves" suffering from the disease, where there was no actual disease, and hence no "tuberculous" toxemia were present.

Two distinct cases somewhat illustrating the above came under my personal observation:

Case II.—A woman 35 years of age who, being in somewhat poor physical health following a confinement, consulted a physician because of a slight cough. The physician, either because of poor skill in physical diagnosis or because the patient had a tuberculous history, diagnosed her case as one of pulmonary tuberculosis in the "early stage" and advised certain hygienic measures. The patient immediately became depressed, greatly worried, and almost melancholic. As often happens, another physician who examined this patient could not find any tuberculosis, following which the patient brightened up considerably, but as she had no reason to accept the negative diagnosis any more than the positive, she consulted a specialist—who, however, was unable to make a definite diagnosis at that time in view of her general physical health, and ordered her to go to a hospital for observation. Because the patient had a tuberculous history her relatives and friends decided that she was suffering from tuberculosis and she was advised to go to California, the only place where she could be cured. This entailed great financial sacrifice as they were rather poor people. The result was marked depression and suspicion; she was suspicious that the real truth about her condition was being hidden from her; she later on developed suicidical tendencies, and to save her from the same she had to be placed in a sanatorium for mental diseases. In the meantime repeated examinations by various physicians assured her that she was free from tuberculosis. She then gradually became more cheerful, gave up her suicidical ideas, resumed the care of her family, and for the last eight years has been in her normal mental state.

Case III.—A woman about 28 years of age, somewhat poorly developed and of a neurotic disposition, consulted a physician for a slight bronchitis; he pronounced her case one of incipient tuberculosis, following which she became depressed, morose, neglected her husband and her home, and continued to spend all the earnings of her husband, who was an ordinary working man, consulting one specialist after another in the city of Philadelphia. As specialists often disagree in their diagnosis it was quite a while until she became convinced that she was free from tuberculosis, when all mental changes disappeared and she resumed her former mode of life.

The above two cases show mental changes not dissimilar to those observed in tuberculous patients, and they certainly were not due to any "tuberculous toxemia."

The one mental trait which I wish to emphasize and which is present to a greater or lesser degree in all individuals predisposed to or actually suffering from pulmonary tuberculosis is fear of the disease and its result—death. Anything that produces nervous exhaustion lowers the vitality of the individual and renders him susceptible to tuberculosis. Fear is a potent factor is producing both. Sherrington[10] states that each individual at any given moment has a limited amount of dischargeable nervous energy. This energy is at the disposal of any stimulus which occupies the nerve paths, resulting in the performance of an act. Each discharge of energy is subtracted from the sum total stored energy, whether the subtractions are made by the excitation of nociceptors, by trauma, by tickling, by fighting, by "fear," by flight, by excitation of sexual receptors, or by any of these singly or in various combinations; if the sum total of the spent energy is large enough, exhaustion is the result. Apparently there is no distinction between that which is due to discharge of nervous energy in response to trauma and that due to other causes.

Crile, in his paper on the origin of emotions,[11] tells us that fear is the psychic representation of injury, and as fear was created by trauma, it, through phylogenetic association, is manifested by reactions similar to those present in response to injury, causing discharge of energy, often leading to complete exhaustion. During fear all functions of the body requiring expenditure of energy and which are of no direct assistance in an effort toward self-preservation, are suspended. Fear or trauma may drain to the last drop the dischargeable nervous energy and therefore the greatest possible exhaustion may be produced by either.

For centuries tuberculosis has been considered and still is considered by some an incurable and fatal disease. The fear experienced by the individual whether when he imagines he is suffering or is actually suffering from the disease, produces a constant drain upon the dischargeable energy, diverting it from other paths as the gastrointestinal, causing various gastrointestinal disorders, and through the law of summation of stimuli produces nervous exhaustion, rendering the individual not affected with the disease more susceptible to it and leading in those actually suffering from it to a more rapid and fatal termination.

II.—The study of the *relationship of pulmonary tuberculosis to insanity* presents many difficulties of a practical nature. The literature on the subject is very meagre; it is comparatively only recently

that more or less complete records of patients are being kept in hospitals for the insane. With the great advances in psychiatry during the last few years it is, of course, natural that the greatest attention is being paid to the mental condition of the patient; the physical examinations are usually relegated to the younger members of the staffs, who, because of lack of experience, often overlook various physical signs, especially those pertaining to tuberculosis. Again, the mental condition of the patient upon admission and later on is often such that no cooperation on his part can be obtained, without which pulmonary signs specially in the early stages are impossible of detection.

The majority of hospitals for the insane still lack special provisions for the treatment of tuberculous patients and there seems quite a reluctance on the part of the medical staffs to pronounce their patients tuberculous, which is possibly due to the unjust opinion among the laity that tuberculosis occurring in insane asylums is due to unsanitary conditions of the hospital or improper care of the patients. In many hospitals no case is considered tuberculous unless a positive sputum has been obtained. Such practices when combined with the infrequent physical examinations of the patients and the impossibility of doing so in many cases because of the patients' negativistic and indifferent attitudes, leave many tuberculous cases undiagnosed. These are in part the reasons why statistics regarding the mortality of pulmonary tuberculosis in equally well conducted hospitals for the insane vary so greatly. Many cases of pulmonary tuberculosis are diagnosed two or three months before death, under which condition the data as to the influence of pulmonary tuberculosis upon the course of the psychosis and *vice versa* are meagre, contradictory, and somewhat unreliable.

Psychiatry has made rapid strides during the last few decades, discarding many theories previously held as to the etiology of various psychoses, and for that reason some of the theories regarding the relationship of tuberculosis and insanity have become automatically defunct.

There was a time when almost every form of neurosis and many psychoses were explained on the basis of toxemia, and it was then quite natural to give the toxemia of tuberculosis a prominent place as a causative agent for various psychoses. The relationhip of neurasthenia and various neuroses to pulmonary tuberculosis has been discussed in an earlier part of this paper, and here I will restrict my remarks to the actual psychoses only. Because of certain similarities in physical signs and other phenomena observed in various psychoses and pulmonary tuberculosis, such as rapid pulse, progressive loss of bodily weight, depression, the hereditary transmission, etc., various writers have been led to see a strong causative interrelationship between insanity and tuberculosis. According to McKinnon,* "the scrofulous and insane constitutions are nearly all alike." Van Der Kolk* states: "Lung phthisis especially, appears to me to stand very frequently in close connection with insanity." Guislain* states that pulmonary tuberculosis appears to be in direct relationship with insanity. It is frequently seen in the progenitors and predecessors of the insane.

*Quoted by Clouston.[15]

Thomson sees a great similarity in the hereditary transmission of these two diseases. Clouston[15] described a definite form of insanity, the etiology, clinical character, duration, and transmission of which were all connected with the accompanying phthisis, and which he called "phthisical insanity." He described in detail various stages of this special form of insanity, giving various symptoms, and so distinct a form did it represent, according to him, that he was able to diagnose it through the mental symptoms alone at a time when no physical signs were demonstrable. According to him, this form of insanity was recognized by such writers as Spitzka, Ball, Kraft-Ebing, Maudsley, Blanford, Buckhill, Tuke and Savage.

Savage (quoted by Clouston[15]) states: "Phthisis in the insane is associated with certain groups of symptoms characterized by suspicion and refusal of food on the one hand and with masking of the phthisical symptoms on the other.

If one reads the description of the mental symptoms of "phthisical insanity" as given by Clouston it becomes quite evident that they represent the mental symptoms of the psychosis now known as "dementia precox." In looking over the statistics of various hospitals for the insane regarding tuberculosis I find that over 50 per cent. of those who died with this disease also suffered from dementia precox. When we bear in mind this point we can understand why Clouston could diagnose "phthisical insanity" from mental symptoms alone. If we should call every case of dementia precox, when no physical signs are demonstrable, "phthisical insanity," we would be right in over 50 per cent. of cases, not at all a bad showing from a diagnostic standpoint.

Some writers, though not accepting Clouston's "phthisical insanity," accept certain of the symptoms described by him as peculiar to the tuberculous insane, and they emphasize melancholia and morbid suspicion as the chief characteristic symptoms appearing in any psychosis upon the development of pulmonary tuberculosis.

Thus Gubb[3] quotes Mott, who states that melancholia is nearly always met with in insane patients suffering from tuberculosis, and the onset of the mental symptoms appears coincidently with the development of the tubercle; and in proof of his contention he calls special attention to the fact that paretics are free from tuberculosis and, of course, melancholia is rather infrequent among them.

Alexander[4] states that the influence of phthisis on any form of insanity is to produce a "suspicional" element not hitherto present.

Milton,[6] on the other hand, quotes Alfred Miller, who gives statistics of the death rate from pulmonary tuberculosis at the Warwickshire Asylum, and he comes to the conclusion that the appearance of pulmonary tuberculosis does not influence the psychosis, and especially emphasizes the fact that none of the patients who died of tuberculosis were melancholic; and this has been his experience for many years.

Other writers express just as divergent views upon the question of the relationship of pulmonary tuberculosis and insanity. Hazen (quoted by Saxe[1]) thinks that tuberculosis is five times as frequent among persons in insane asylums than among sane

persons, and that insanity among tuberculous individuals observed in London hospitals is more frequent than among other classes of patients in the same hospitals, and he explains it on the basis of the toxic theory of tuberculosis. Van Der Kolk (quoted by Kiernan[3]) and Alexander[4] state that insanity alternates with phthisis, mental symptoms being most marked when the tuberculous condition is latent; the disappearance of the mental symptoms is followed by reappearance of pulmonary symptoms.

Kiernan[3] holds that insanity modifies existing phthisis—cough, rise of temperature, and other marked symptoms being as frequently absent as present in insanity.

Saxe[1] quotes Chartier and Caulex, who have observed increased sexual irritability in the tuberculous insane, even satyriasis and nymphomania. He does not think that there is an especial form of insanity peculiar to tuberculosis.

The above diverse views as expressed by the various writers is due to their different conceptions regarding tuberculosis and the etiology of the psychoses. Some writers would consider every case manifesting certain physical signs of the chest as tuberculous, and such writers in examining patients suffering from any psychosis presenting certain physical signs of the chest, but who are free from such symptoms as cough, fever, loss of weight, etc., attribute this "peculiar" course of tuberculosis to the influence of the psychosis.

Again, those writers who uphold the theory of toxemia as the cause for most of the psychoses will, of course, see in tuberculosis a strong etiological factor in the production of many psychoses. Modern views of tuberculosis and phychiatry show the above to be fallacious.

It is held by most authorities on tuberculosis that the tuberculous infection occurs principally during childhood; that probably few individuals escape it, and that in later years there is an activation of that infection. During the interval, however, such individuals cannot be considered tuberculous. Again, during adult life some individuals suffer from definite active lesions of tuberculosis which become healed or arrested with or without treatment. Such individuals may live for many years and die of some disease other than tuberculosis; however, during those many years physical signs of tuberculosis were always absent, and they, of course, could not be called tuberculous; the appearance of a psychosis during such an interval could not, therefore, be due to any tuberculous toxemia, as the individual was no more suffering from tuberculosis at the time than an individual having a second attack of pneumonia, after a more or less long interval, could be considered as having suffered from pneumonia all the time. Depending upon the variety of the psychosis, whether it lowers the vitality of the individual or not, the old lesion may or may not become activated. In some cases where the psychosis does not sap the individual's energy too much, the tuberculous infection has a much better chance of becoming arrested or healed, due to inability of the patient to dwell on his symptoms and worry about his condition.

It has long been recognized by those experienced in tuberculosis that many symptoms observed during the course of pulmonary tuberculosis, such as the constant hacking cough, occasional rises of temperature, and even losses of weight are not due to the disease, but to the patient's constant thought and worry about the disease. I have often seen several hundred patients watching an entertainment or listening to an address "forget" to cough for hours, but who otherwise coughed all the time, and in a similar way other symptoms disappeared when their attention could be diverted toward different channels, and this is just what happens during a psychosis, but not because the psychosis has any direct beneficial influence on the disease.

That insanity is more frequent among the tuberculous is disputed by many writers. During my several years' experience in a sanatorium of 1,100 patients I have not observed one case developing a definite psychosis, though I have observed various degrees of confusion, vague delusions, and impaired judgment during the last stages of the disease. Tuberculosis involving the nervous system is, of course, excluded from this discussion.

McCarthy (quoted by Carncross[2]) reports that out of 885 tuberculous cases 20 showed mental disturbances; they all occurred in the far advanced cases. Confusion was present in most of them; loss of memory and depressed physical tone were responsible for the confusion.

Tuberculosis may be considered as an etiological factor in the production of a psychosis in so far as it acts as an additional difficulty in the life of an individual who was at the breaking-point, whose successful adjustment to his environment depended upon a fine balance, and the knowledge that he was suffering from tuberculosis was sufficient to turn the scales resulting in complete inability of adjustment and hence a psychosis. In no sense must we consider tuberculosis as an etiological factor in the production of psychosis because of the "tuberculous toxemia."

As to the greater prevalence of pulmonary tuberculosis among the insane, statistics as presented by various hospitals are contradictory and unreliable. My impression is that it is greatly exaggerated. If insanity were as strong a factor in producing tuberculosis as is held by some, this should be evident through a more rapid course of the disease, and as I will show later through statistics gathered at the Government Hospital for the Insane rather the opposite appears to be the fact.

Bondurant (quoted by Alexander[4]) states that his autopsy results show that while one-half of the insane negroes contract tuberculosis, one-third make a very good stand against the disease, either entirely recovering or living for years, and, according to Alexander,[4] the prognosis in the white insane is much more favorable.

The tuberculous figures studied at the Government Hospital for the Insane, while not absolutely conclusive, are quite interesting as indicative in a general way of the frequency of tuberculosis among the insane and also as to prognosis under favorable conditions.

The Government hospital has five cottages for the treatment of tuberculous cases. Each cottage has twenty beds and represents a modified and much improved Loomis shack. They are located away from the larger buildings, surrounded by fine

lawns, and so placed that they have at all times a maximum amount of air and sunshine available.

At the present writing there are in the institution 3,274 patients, divided as follows: Males, 1,986 white, 417 colored; females, 548 white, 323 colored. Of that number 84 are cases of pulmonary tuberculosis.

In the majority of cases tubercle bacilli are present in the sputum, in others the disease was diagnosed clinically from the symptoms and physical signs. In 16 cases the disease was diagnosed either upon admission or within the first year after admission, and among them 3 were incipient, 9 moderately advanced, 4 far advanced. In the rest of the cases the disease was diagnosed at periods, following admission, ranging from 3 to 27 years—in the majority of cases 8 to 10 years following admission.

For the purpose of studying the progress of the disease, I divide them into three groups:

1. Inactive: Cases in which the disease is either arrested, or apparently arrested, as indicated by absence of râles upon physical examination, and by absence of cough, expectoration, or fever. The majority of this group show a decided gain in weight, while in some the weight is stationary.

2. Moderately active: Patients who have slight or no fever at all, but who either cough, expectorate, or through slight loss of weight or presence of râles in their chest indicate some degree of activity of the tuberculous process. Almost all of this group are up and about.

3. Progressive: Cases in which the disease is progressing more or less rapidly to a fatal termination, presenting the usual symptoms of active cases. Of this group all are bed patients.

The 84 cases are divided as follows: 7 incipient, all inactive; 55 moderately advanced; 46 inactive, 9 moderately active; 22 far advanced, 7 inactive, 9 moderately active, 6 progressive.

The duration of the disease in the cases since the time of diagnosis varies from several months to 16 years; in the majority of cases the duration is from 5 to 8 years.

Most of the cases show a gain in weight averaging 10 pounds within a short time after admission to the tuberculosis cottages, after which the weight remains stationary or fluctuating within 3 to 5 pounds. Quite a phenomenal gain in weight occurred in a colored woman 27 years of age, suffering from dementia precox. Upon admission she was found to be suffering from pulmonary tuberculosis in a moderately advanced stage, the disease being fairly active. During her 3½ months' stay here she gained steadily in weight, altogether 28 pounds, and is still gaining. I am not presenting this isolated case in proof of anything special, but simply to indicate the possibilities of the tuberculous insane when placed under favorable conditions. The results of treatment as given above would compare favorably with the results of the average sanatorium for the treatment of tuberculous individuals not insane.

The mortality among the tuberculous insane, at least as observed at the Government Hospital, does not seem to show any unusual increase as compared with the tuberculosis death rate among the sane population. The 1900 census of the United States gives 109.9 deaths from pulmonary tuberculosis in every 1,000 deaths from all causes, or 11 per cent.

At the Government Hospital for the Insane between the years of 1910 and 1916 inclusive, there were 1,852 deaths from all causes; of this number 213 died from pulmonary tuberculosis, or 11½ per cent. During the last ten years the death rate per population was 10 deaths from pulmonary tuberculosis per each 1,000 patients.

Osler,[19] in speaking of the decrease of the death rate from pulmonary tuberculosis, states that in five New England cities the death rate was decreased from 30.7 to 21.4 per 1,000 population, and in several cities of the Middle States from 31.4 to 23.4 per 1,000. So that 10 cases per 1,000 certainly does not indicate that tuberculosis is specially rampant among the insane.

While I will admit that some deaths at this hospital from pulmonary tuberculosis are overlooked, I do not think the death rate is quite as great as in the average city among the not insane patients.

We must also bear in mind that our hospital has quite a large percentage of colored patients, which would, of course, tend to increase the death rate from tuberculosis. The mortality for the last few years since the tuberculosis cottages have been opened shows a still smaller death rate than given above.

The most interesting feature, to me at least, in the study of the tuberculous insane, is the variety of psychosis most prevalent among them, or, in other words, the psychosis which is more vulnerable to pulmonary tuberculosis.

The following are the various psychoses among the tuberculous patients:

Paresis	1
Psychosis associated with epilepsy	6
Psychosis associated with imbecility	6
Psychosis associated with alcoholism	1
Psychosis associated with organic brain disease	1
Psychosis associated with cerebral lues	1
Undifferentiated dementia	2
Undifferentiated depression	1
Manic-depressive psychosis	2
Paranoid state	1
Arteriosclerotic dementia	2
Dementia precox	60
Total	84

Here we see that out of 84 cases 60 belonged to the dementia precox group, or 71 per cent. of all cases. The female patients gave a somewhat higher percentage of precox cases than the males. In the white and colored patients, the percentage was about the same. All forms of precox were represented in this group, the catatonic giving a slightly higher percentage than the other forms.

In studying the above cases, I failed to observe any influence pulmonary tuberculosis has upon the psychosis. I absolutely failed to observe any "alternation" between the two conditions as reported by Alexander and Van Der Kolk, above mentioned.

The frequent absence of cough, expectoration, and fever is rather due to a negative influence of the psychosis upon the disease, as the above symptoms, so frequently observed among the not-insane tuberculous patients, are often due, especially in the first and second stages, not to the disease itself, but, as pointed out above, to constant worry and dwelling on the symptoms of their malady. The individual suffering from a psychosis is too busy with his delusions and hallucinations, and hence he "forgets to

cough," and the state of lowered vitality in which these patients usually are accounts for the absence of fever; the body has no great amount of energy to react against the foreign protein—the tubercle bacillus.

Since dementia precox cases form the largest group among the tuberculous insane, it is quite natural to find such symptoms as depression, suspicion, seclusiveness, and refusal of food among them, but the same symptoms are found just as frequently among the dementia precox cases free from any tuberculous infection, hence we cannot attribute the presence of those symptoms to the influence of pulmonary tuberculosis upon the psychosis as some writers would have us do. A clear conception of dementia precox would certainly help to explain many apparently contradictory statements regarding pulmonary tuberculosis and various psychical phenomena mentioned in the first part of this paper.

The scope of this paper will not allow me to discuss dementia precox in detail nor is this the subject of discussion, but I wish to emphasize certain points in relation with this condition in so far as they throw some light upon the subject at hand.

White[20] states the following about dementia precox: "Every individual born into the world has, if it could be determined, a definite potentiality for development. The force of the impetus which starts it on its path is sufficient to carry it a certain definite distance. The predetermined goal in each case will be reached if no accident intervenes to prevent. In the subjects of this disease the 'original' impetus has been weak, only sufficient to carry them a short way, and when its force is spent development stops and the retrograde process is hastened or perhaps immediately initiated by some special physical or mental stress occurring at the critical point of puberty and adolescent evolution."

It is possible in many cases, from the behavior of such individuals during early life, to foretell many years before that they will develop a dementia precox psychosis, and there has come to be recognized a certain type of personality known as the precox personality. Such individuals belong to the so-called "shut-in" type; they do not meet difficulties openly and frankly; they are seclusive, given to dreaming, indulge in phantasies, and have great difficulty in accepting reality. By reason of faulty environment and bringing-up they have developed certain desires, wishes, and attachments, which later in life they cannot achieve and hold, as they do not meet with the approval of civilized society. Such individuals have no especial goal to aim for, but live in a world of dreams, away from reality, satisfying their wishes and desires—they are "introverted," and under stress of any serious difficulty in real life are completely thrown out of gear, developing a psychosis, withdrawing themselves completely from reality and living in a world where their aims and strivings are all or in part accomplished through psychical representation of the same. Not all individuals belonging to the "precox" personality, however, develop dementia precox in a recognizable form. Many under certain favorable circumstances are able to adjust themselves in an imperfect manner, constantly struggling with their difficulties, being frequently at the "precipice" of an actual psychosis. Such individuals are usually in a state of lowered vitality and specially prone to pulmonary tuberculosis, which accounts for the description of many mental traits observed by many writers in the so-called "susceptible to tuberculosis" individuals. Whereas in reality the various mental traits, as lack of fixity of purpose, periods of apathy alternating with feverish activity, suspicion, emotional instability, are traits genetically predetermined through heredity and environment, and the tuberculous condition is rather the effect than the cause of the same.

Cause and effect are frequently confused by various writers on the subject of tuberculosis and mental traits. Some writers see in tuberculosis a certain factor in the production of criminal tendencies. Fanoni[21] reports cases where tuberculous individuals expectorated promiscuously with intention to infect others, and Gilbert (quoted by Fanoni[21]) reports a case of a man who made his wife drink champagne into which he expectorated tubercle bacilli. It is through such isolated cases that some writers seem to emphasize the rôle of tuberculosis in leading toward criminal acts. Isolated cases of such character have been observed among syphilitics and the subjects of other pathological conditions. Such individuals were undoubtedly decidedly psychopathic if not suffering from an actual psychosis, and tuberculosis is certainly not a causative factor in such cases.

Because tuberculosis is frequently observed among criminals some writers conclude that tuberculosis tends to produce criminal tendencies, but they, of course, confuse cause and effect.

To understand properly any mental traits or phenomena in the life of an individual, we must consider them as end results to be understood only by understanding the past out of which they grew and of which they are an expression.

Conclusions.—1. There is no special psychology peculiar to pulmonary tuberculosis.

2. Neurasthenia and other neuroses are not caused by pulmonary tuberculosis, nor are they present in the majority of tuberculous individuals. By lowering the vitality of the individual, neurasthenia and the other neuroses often act as an indirect cause in the production of pulmonary tuberculosis.

3. Pulmonary tuberculosis acting as a serious difficulty in the life of the individual will produce certain reactions, which will be reflected through the psyche, depending upon the previous characteristics of the individual and his environment at the time of the disease.

4. I have failed to observe that, as claimed by various writers, selfishness and disregard for others is especially frequent among the tuberculous. When observed they are not due to tuberculosis, but to other genetic factors, which shaped the personality of the individual.

5. The one mental phenomenon common to a great majority of tuberculous victims, or present in those who have a hereditary or physical predisposition to the disease, is fear of the disease and its result—death. Some are quite unconscious of it; others deny it though quite aware of it.

6. Though pulmonary tuberculosis is not responsible for the many psychical phenomena observed in

sufferers of the disease, the psychological side of the patient should not be neglected. The patient's difficulties must be studied carefully and a way of removing them as far as possible must be found, as their presence, and especially that of fear, under which the patient may labor, saps his vitality, so necessary to the system in order to defeat the disease.

7. The spread of the modern and true ideas regarding the hereditary transmission and the infectiousness of pulmonary tuberculosis among its victims and also among the healthy members of the community will help to remove the exaggerated and almost morbid fear of the disease, and to establish a more humane attitude on the part of the healthy individuals toward the sufferers from the same, thus acting as a potent prophylactic factor in diminishing the mortality from pulmonary tuberculosis.

8. Pulmonary tuberculosis is not a direct cause of insanity, though in some cases it may act as the proverbial last straw on the camel's back.

9. There is no special form of insanity peculiar to tuberculosis.

10. The appearance of tuberculosis during the course of a psychosis does not modify the latter to any extent.

11. Dementia precox, by lowering the vitality of the individual, is the most frequent indirect cause of pulmonary tuberculosis among the insane.

12. Every hospital for the insane should have special provisions for the care of tuberculous patients. The modified Loomis shack, as adopted by the Government Hospital for the Insane, is most admirably suited for this.

13. In the modern hospitals for the insane, where special provision is made for the treatment of pulmonary tuberculosis, as good results may be obtained in arresting or curing the disease as in special sanatoria for tuberculosis.

14. By more careful attention to the physical condition of the patients in hospitals for the insane, through repeated chest examinations and frequent weighing of suspicious cases, especially precox cases, the tuberculosis mortality may become greatly reduced and many cases may be indirectly helped out of their psychoses.

OBSTETRIC FADS AND HERESIES.

BY EGBERT H. GRANDIN, A.B., M.D. (HARVARD).

NEW YORK.

LIFE MEMBER OF THE OBSTETRICAL SOCIETY OF NEW YORK.

AFTER a protracted rest from my accustomed pursuits, I am once more at the helm, and I find the obstetric art cumbered with much that is new and helpful, but also with many rank weeds—fads and heresies which must cause my masters in obstetrics to stir uneasily in their graves. For forty years I have been a student of this art, and my teachers were giants in their days: Reynolds and Buckingham of Boston, Tarnier of Paris, Robert Barnes of London, Karl Braun of Vienna, Schauta of Prague, Welponer of Trieste, Isaac E. Taylor and Fordyce Barker of New York. These were my teachers, and the grateful pupil lays to-day, after the lapse of forty-five years, a sprig of evergreen on their graves. These men lacked but one thing which we possess to-day—asepsis in obstetrics. Another teacher of mine, Oliver Wendel Holmes, the predecessor of Semmelweis, had indeed written his thesis on puerperal fever, but his views had fallen on uncultivated ground. These teachers of mine were masters of the forceps and of version. They laid down with accuracy the limitations for the induction of premature labor. They believed, while conserving the vital energy of both mother and child, in giving Dame Nature a chance; and, barring the mortality rate due to lack of knowledge of asepsis, their results have not been surpassed. One of them, Tarnier, at the Paris Maternité, taught me how to use the axis-traction forceps, an instrument of incalculable value when properly applied within its limitations. I have labored for years vainly to persuade the profession to use this instrument, for without it, I maintain, obstetrics cannot, within the sphere of the instrument, be practised properly. And yet only the other day a professor of repute told me that he did not find scope for it, and that his colleagues agreed with him!

The introduction of asepsis into obstetrics has enabled us to improve upon the work of these masters of the olden days. At the time when it was my privilege to work at the New York Maternity Hospital, now the maternity department of the City Hospital, the mortality rate from puerperal septicemia ranged around 10 per cent. In a rural cemetery of a town in North Carolina lie interred the remains of my old colleague, Henry J. Garrigues, and on his tomb there are inscribed the words, "He introduced antiseptic midwifery into America."

This man "builded unto himself a monument more lasting than brass," and enabled us at the Maternity Hospital to lower the mortality rate from septicemia to one-eighth of one per cent. Again I lay a sprig of evergreen on the tomb of a master obstetric mind.

These prefatory remarks are offered, not in an egotistical spirit, but purely that force may be added to my words as I start to point out to those who know me not, and to those who perchance have forgotten me, my reasons for rejecting the fads and the heresies which are attempting to thrive to the detriment of my specialty. Like Rip Van Winkle of olden time, I stand aghast.

The first fad I note is the so-called "Twilight Sleep." Emanating from that land of myth and fiction along the shores of the vine-clad Rhine, it was introduced into America properly labeled, like other German patent medicines and tinware and matches. The American indorsers chose a popular magazine for advertising purposes, and women cried for it and professors boosted it! Like the moth, the Lord be praised, it has died the death to which, for the nonce, all things Hun are doomed, and to-day I cannot find a single practitioner of repute who uses the method. Why it ever gained foothold passes my comprehension, unless the profession, sated with old-time methods of repute for allaying the anguish of childbearing, is, like the Greek, hunting for a new God. Buckingham and Reynolds and their pupil Richardson taught me better, and, withal, a method which does not carry a mortality rate, nor an infantile death rate, such as, on investigation, will be found associated with twilight sleep. In the fourth edition of my "Practical Obstetrics" I analyzed the statistical data culled from German sources, and I showed that these data damned the method. Avoid, my medical brethren, the folly of extremes, and hold fast to that which is good. Use chloral freely, and be not afraid; resort to morphine and atropine with judgment; administer quinine judiciously after the contractions are well under way; be not afraid of chloroform; do not delay the application of the low forceps after a timely fashion. Thus you render labor as nearly painless as our present knowledge permits, without subjecting woman or child to the dangers inevitably associated with the use of morphine, hyoscine and scopolamine.

The next fad I note is the cesarean-section craze. It was my fortune to perform the early cesarean sections from an *electice* standpoint; that is to say, under the relative indication, at the New York Infant Asylum and at the New York Maternity Hospital in 1889-1890. My thesis for membership in the American Gynecological Society bore the title, "A Plea for the Cesarean Section from an *Elective* Standpoint." After the lapse of twenty years, with the experience thus gained, I can preach the same sermon to-day. *Festina lente*, my obstetric friends! To show the extremes to which certain rabid cesarean sectionists will go: A number of years since an assistant of mine called on me, greatly perturbed because a professor had advised the section on his wife for the reason that in the previous labor she had suffered from uterine inertia! The pelvis was normal, the presentation L. O. A. I quieted my young friend, ordered strychnine, gr. 1/40 t.i.d. for six weeks precedent to labor; when the contractions became active, chloral in 15-grain doses every three-quarters of an hour until 60 grains had been administered; quinine, 15 grains at one dose. In fourteen hours the woman delivered herself of a splendid boy weighing 13 pounds. The woman has no scar on her belly; she did not run the modest 4 per cent. risk associated with the cesarean section; the professor was unable to notch his cesarean-section rod. I have carefully analyzed the series of sections recorded by a number of operators, and it's "dollars to doughnuts" that Tarnier or Isaac E. Taylor, if alive, could cut the series at least 30 per cent. I wonder if some of these operators are trained in the technique of version, if they own the axis-traction forceps, if they have relegated the induction of premature labor to the ash heap!

Another fad is this question of birth control. This question need never have arisen. In my professional career I have never hesitated, after due consultation, to induce abortion where otherwise the life of the woman was imperiled. This course I shall continue to follow. So far, I have escaped Sing Sing, although possibly, according to a certain religious belief, I may spend a few years in purgatory. If so, I shall certainly find very congenial company. The daily press—sometimes to the exclusion of war news—has exploited this advance guard of woman suffrage. To the medical press I would say that neither man nor woman should be entitled to procreate more children than they can rear. The doctrine I preach is not that of birth control, but that of *sex repression*. Neither men nor women should be allowed to make animals of themselves, and I apologize to the animals in remembrance of the fact that they are continent except during the rutting season. Followed to its logical limit, "birth control" allows men and women to copulate without sanction of law or of clergy. The women will "sin" all the more frequently because of lack of fear of the consequences. The man will remain the same rascal he has been, sexually, since in the garden of Eden Adam laid the blame on Eve.

The last fad I note has been of gradual development. My dear "young" friend Father Abraham Jacobi must smile in derision as he witnesses the evolution of the scheme which will gradually eliminate woman as a nursing animal and place the infant at the mercy of modified milks and patented foods. The glory of woman's crown is motherhood. The crown is incomplete unless lactation forms the central jewel. I will not go so far as to state that every woman can be made to nurse her babe, but I will maintain that every woman should who can; that she is unworthy of being a mother if, able so to do, she does not; and I would emphasize the fact that, structural mammary development or inherited or acquired disease being absent, I can make 95 per cent. of my patients nurse their infants. A phase of this fad is to make the newborn child lengthen the nursing interval from two to three hours; fitting, as it were, the gastric capacity of the infant to the desire of the mother to, let us say, play bridge or go to the "movies." Read and mark and digest, ye iconoclasts and reformers! Read Father Abraham Jacobi's work on infant

feeding, a classic always, and consult, incidentally, the chapter on the care of the newborn infant, in Grandin's "Practical Obstetrics."

Do the least harm, my medical friends, to woman and babe; *study the methods of the past, hunt less eagerly for the new goods of foreign make;* then, with asepsis as its keynote, you may reasonably hope to match the record of the master minds which has been my beacon.

200 West Fifty-eighth Street.

A SIMPLE METHOD OF FORMING ORIGINAL MENTAL ASSOCIATIONS.

(PRELIMINARY COMMUNICATION.)

By EDWARD PREBLE, M.D.

NEW YORK.

While making experiments with accidental grouping of words the author became impressed with the suggestive and stimulating influence of this exercise upon the mental processes. In a search for some kind of a method for the rapid selection of word groups he was led to extemporize the words from sets of letters assembled by chance. It was learned that a set of 15 or 16 letters represented an optimum, for a smaller number can hardly guarantee a proper balance of vowels and consonants, while with a larger number the possibilities would increase so rapidly as to be confusing. The letters, readily selected by the aid of some mechanical device, were assembled in rows, three of five or, better, four of four words each, and but few seconds of time were required. Thus:

n h u i
d e n g
m p k f
b r e l

It would be manifestly crude to give every letter of the alphabet the same value; hence, x, q, z, etc., were given secondary values as vowels; u, v and w were made interchangeable, as were also i, j and y and k and c. Similar license was suggested from time to time.

To obtain the words for a group we seek for the nucleus or stem of a word in some line and build it up with letters from the other lines. In this manner we readily obtain a word "breeding." From the remaining eight letters "punch" is readily selected (if we value k as c). The two words as they stand have no obvious significance. But words have many meanings—literal, metaphoric, technical, etymologic, symbolic. If we use breeding in the sense of manners or behavior and punch (Mr. Punch) in the sense of buffoon, the significance is obvious but possesses no element of novelty. We make a second attempt and understand breeding in the sense of increase or multiply. In seeking for a meaning of punch which will make sense we recall that punch, the beverage, a Hindu word, literally means five, the number of its ingredients. The group "increase (or multiply), five," commonplace in itself, suggests the subject of a five child system as a necessity for the repopulation of the warring countries, which are becoming unpeopled from high mortality and low natality. This is not a mere abstraction for, according to Professor Jayle, a large percentage of French women are willing to bear from four to six children if the State will aid in raising them. This example is given merely to show how a casual association of words can conjure up one of the most momentous questions of the age and rudely dissolve the mental association, in the provident, of marriage with one or two children. This association has not yet become a fixed habit of thought, although moral parental obligation has generally been limited to making good the normal losses from death. One feels certain that the Teutons, whatever the outcome of the war, will spare no measure which can aid in repopulation of the Central Empires, and thus the problem will be passed on to their enemies.

The jumble of words, "twist, lamb, car," led by steps not necessary to detail to the idea of sheep as beasts of burden or draught. As far as can be ascertained it is only in Thibet that they have always been used to carry light loads in localities where roads are wanting. Other wool and hair bearing animals seem to have been employed freely for burden purposes, and the goat readily pulls a load. Such use of sheep would naturally be very limited. Reasons for the absence of such usage would doubtless be founded almost wholly on *a priori* considerations. According to grooved thinking, a sheep is an animal which supplies wool and mutton and is not intended by Providence for milch and draught purposes. While in some countries ewe's milk is largely utilized for making cheese, the present milk shortage seems to have awakened no thought of such a possibility. The ready answer that these two employments of the sheep would not pay doubtless holds good in the main, but not for exceptional conditions. It should not be difficult to train a lamb to carry a pannier.

The association "third hinge" led to the surprising discovery that the average man firmly believes that a door must necessarily have but two hinges. If you tell him he passes daily through entrance doors with three hinges he will refuse to believe you. A specially well informed man will perhaps make the statement that a heavy door sometimes has an extra hinge, but in reality the number of hinges seems to be only the whim of the builder who may put three on a flimsy door while an exceptionally strong one often has but two. Once a man notices the middle hinge, overlooked all his life, it looms up very large.

While words groups may be formed with no particular problem in the mind, they are far more suggestive as a rule if the person is at work upon some fixed objective. So startling and uncanny are they at times that one might be pardoned for thinking that he had stumbled upon a rival of the ouija board or gazing crystal as a revealer of unconscious mind. But owing to the method used there is little opportunity for the exercise of such a faculty. The aim has been rapid mechanical selection of words, and no time is wasted in mulling over them. If they suggest nothing a new set of letters is assembled.

In imagination we have placed ourself in the mental attitude of all sorts of individuals confronted with their own personal problems. Some of these are of wide or universal interest, others concern only the individual. In the present connection we limit our activities to some of the problems of the

physician. A small matter, but one which often worries him greatly, is a subject for a medical paper. He may skim through an index of a book or bound journal or look over programs of meetings a decade old or run through the titles in the Surgeon General's catalogue, yet find no hint of what he wants. Old Use-and-Wont has done his deadly work, and most of the possibilities mean old grooved associations. He obtains a series of groups: "Waif, go, land" at once suggests "orphan goes to the country." This means nothing at first, but if he look into the matter he will find a forward movement on foot for taking orphans out of the costly institutions and placing them in rural homes. The group "heart, dip, bulls" suggests "ludicrous mistakes about the dip or inclination of the heart." This in turn suggests dextrocardia and failure to recognize it, and in a wider sense errors made in regard to the apex beat under all conditions. Many a bad condition is overlooked because the apex seems to be in its normal position. The writer believes that a suggestion which comes in this way will be more likely to be acted on than one which comes through another's mind, for men who are self-reliant do not welcome suggestion even when they solicit it. Another group, "mind, lure, feud," at once suggests the lure or fascination of the psychic motivation of bodily infirmities and the schism which results between adherents of this concept and those who uphold physical causal factors of disease, as to the relative importance of each element in pathology as a whole.

The great majority of these word groups have some suggestive power. Even such an unpromising one as "true, sieve, furl" is not an exception. "Furl," to roll up and fasten, suggests a bandage; "true" correct apposition, and "sieve," fenestration. The search should be continued along this line until a satisfactory subject or title is reached. The author, in connection with research for others, has repeatedly made use of this process with prompt results. If the medical man wishes to take up some subject for original research or should he have a desire to produce a book on some novel subject, he can look forward to the same kind of assistance. He may wish a subject for the lecture platform, or, chosen as toastmaster at a feast, he may wish to give out some novel toasts. Called upon to address school children, he may long for some precepts which are not hackneyed. On the other hand, he may be puzzled to invent a name for his summer villa, motor boat, breeding animals, pets, etc. The prodigality of results obtained by these chance groups seems far greater than the spontaneous product, even of a number of minds. Let us suppose that a medical man will be called upon to address school boys or young men. He gets a word group "dare, bunt" and realizes that with his entire audience deeply versed in baseball vernacular he can successfully apply the idea to the daily problems of life.

Suppose he has to deliver an oration or write an article for the lay press. He obtains a group "is both pith sewage" which calls up in the mind many of the geniuses of the world and the Jekyll-Hyde conception of human nature. If he will consult the most recent views of psychiatrists he will find that most of the remarkable men who have been loosely styled psychopaths, degenerates, dipsomaniacs and psychic epileptics may now be better termed manio-depressives. The view is a practical one which tends to harmonize the most divergent opinions of the past. During the profound and prolonged periods of depression men of this stamp should be interned and treated. While in their exalted moods their genius should be fostered and wild extravagances of conduct nipped in the bud by prompt intervention. Very many changes can be rung on this theme alone. The doctor's hobby of the day is history and biography, and in the latter connection especially personality is all important.

But word groups can do much more than give ideas. By forming an entire series of them there is sometimes seen a sort of concordance or synergism. They seem to point to a common goal or to have a common burden. They furnish at times an argument, at other times a vivid description. That the suggestion must vary greatly with the individual is not a drawback but is highly desirable. It must be borne in mind that substance and not form is desired. There is no limit to individual initiative either in obtaining or in deciphering groups, and the only fixed precept is that no letter in a set should be used more than once.

Since this small effort is intended only for suggestion nothing can be gained by increasing its length. The possibilities of word group suggestion are unbounded and the method itself is inexhaustible. No claim is made of originality, for word groups have been used extensively in association tests, although perhaps not when selected by chance. The method has little in common with anagram making, for in the latter a word or group of words is transmuted to a complete word or group, all the letters being employed. In our method complete anagrams are not sought, but only a word or group which can be quickly isolated from the "pi" of sixteen letters.

At its worst this line of effort should be more praiseworthy than the doping out of ancient prophecies or discovery of Elizabethan ciphers. It is recommended to solitaire devotees and would-be "new thoughters" who by its aid may be led to form really new mental associations.

THE COMPLICATIONS OF MASTOIDITIS.

By J. MORRISSETT SMITH, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF OTOLOGY, NEW YORK POLYCLINIC HOSPITAL; ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY.

The study of the complications occurring in the course of an infection of the mastoid process of the temporal bone is one of the most interesting subjects in otology.

With a purulent otitis media and mastoiditis present, it is possible to have the infection extend or to be carried by the blood to almost any part of the body, but as a rule the resulting complication is usually one or more of the following conditions—meningitis, erysipelas, pneumonia, thrombosis of the lateral sinus, and an adenitis, especially of the glands in neck of children, and less frequently brain ab-

scess and labyrinthitis—the two last named conditions occurring, in the majority of cases, in the presence of a chronic infection.

Nature's warning of an extension of the infection is practically always a chill, accompanied by a sudden rise in temperature, and it is just at this point that it is most difficult to determine the point of election of the invading organism, since we may have a beginning erysipelas and at the time of the initial chill and rise in temperature the wound shows none of the characteristic symptoms of redness, burning, swelling, etc., or a beginning pneumonia, with the physical signs still masked, an incipient meningitis with a negative Kernig sign, no stiffness of the neck, etc.

At this stage the best key to the situation is a white blood count, for the following reasons: Given a total white count of thirty thousand or more cells to the cubic millimeter, we immediately suspect a pneumonia; a total count of around twenty thousand, a meningitis or erysipelas, the count being a little higher in meningitis than erysipelas; a count between ten and twelve thousand a thrombosis of the lateral sinus; a true leucopenia possibly malaria, typhoid, or tuberculosis.

At this point I want to state that I do not think that enough importance is attached to the diagnostic value of a total white cell count in cases of infection of the lateral sinus. I have made it a point to follow quite a number of such cases at the New York Eye and Ear Infirmary, and almost without fail the count has been around twelve thousand where there was no other complication present. The value of this procedure is inclined to be underestimated by many, because a ten thousand cell count is so close to normal (from six to eight thousand) that is true in cases when the temperature is normal, but a different proposition entirely when we have a temperature reaching 106°.

The one condition which simulates the temperature curve of thrombosis of the lateral sinus the most is that of a malarial infection, and in that case we get a leucopenia, and it is undoubtedly true that there are too many general practitioners, as well as otologists, treating cases of infection of the lateral sinus for malaria and typhoid fever.

To summarize, given a sudden rise in temperature and a total white count indicating a true leucopenia, then we may suspect malaria, typhoid, or tuberculosis; a count around ten thousand a thrombosis of the lateral sinus; a count around twenty thousand erysipelas or meningitis, and thirty thousand or more a pneumonia.

Next we carefully study the temperature curve. If we have a sinus thrombosis present then the temperature will suddenly jump from about normal to one hundred and five or six, returning close to the starting point within twenty-four hours, with a repetition of this in the following twenty-four hours. If a pneumonia, meningitis, or erysipelas is present the temperature usually ranges between 103.5° to 105°. Of course in the terminal stages of a severe case of any one of these it may be higher.

Now, suspecting a thrombosis of the lateral sinus, we immediately order a blood culture, remembering that we may get a negative culture, due to the fact that the sinus is completely blocked by the clot. This usually occurs in cases of long standing. Another rather important point is the fact that the patient's mind remains clear in spite of the high temperature, in contradistinction to what occurs in meningitis, where the patient usually becomes delirious in from twenty-four to forty-eight hours. Also, there is usually an absence of pain or headache.

Suspecting an erysipelas, an examination of the wound shows, in a very few hours, the tense, fiery-red swelling which, together with the burning pain and progressive line of demarcation, leaves us in no doubt as to the diagnosis.

If we suspect a pneumonia, in a very short time the increased respiration, cough, bloody sputum, pain in the chest, together with the physical signs, make the condition certain.

A meningitis being suspected, a lumbar puncture should immediately be done, taking care that no blood is obtained in the specimen, so that an accurate cell count may be had, and with a cell count of five or six cells per cubic millimeter, a reduction of Fehling's solution, together with a negative globulin reaction, we can be pretty sure there is no involvement of the meninges at this time, especially in the absence of stiffness of the neck, a negative Kernig sign, and no delirium.

In case we have a meningitis we can be sure when it becomes diffuse that the afternoon of the second or third day will show stiffness of the neck, marked headache, and delirium, quickly followed by death. It is important that the Kernig sign be tried, because it will be present, to some extent, before the above symptoms are so marked.

I think it is true in a certain number of cases that we get a marked headache, due to a localized involvement of the meninges, such as may be present in an epidural abscess, but in this case the symptoms of a diffuse meningitis are not present and a lumbar puncture is negative if cultured but may show an increased cell count.

It is well knewn when we have a true abscess of the brain it may be present for several years, and so well walled off by nature the patient has practically no symptoms. The pulse and temperature staying around normal or subnormal, and when the temperature and pulse go up to any marked degree, then we can be pretty sure that the abscess is beginning to involve the meninges either by rupturing into the ventricles or by breaking through nature's protecting wall at some other point.

A lumbar puncture in a true brain abscess will usually be negative, and when it does show positive results means brain abscess plus meningitis.

The question of labyrinthitis, while rather a rare complication, is a very important one. This is especially true in acute cases of long standing, where the infection has involved the perilabyrinthian tissues, causing nausea, vomiting, vertigo, nystagmus, headache, in fact practically all the symptoms of a purulent labyrinthitis, but an examination shows an active labyrinth, while with a purulent labyrinthitis the labyrinth will be dead.

In the perilabyrinthitis the prognosis is very good and a complete exenteration of the mastoid cells results in an early recovery, while a purulent labyrinthitis would require a labyrinth operation and would necessarily offer a more grave prognosis.

Again, we must not lose sight of the fact that a

sudden rise in the temperature may be due to an involvement in the other ear, especially in very young children, or later, and we must always eliminate this possibility.

There is one other complication which deserves special mention, and that is diabetes, it being prevalent especially in those cases of mastoiditis where the *Streptococcus mucosus capsulatus* is found, and an analysis of the urine for sugar should be made in all cases where this type of infection is present.

A perisinuous abscess gives practically no symptoms by which we can diagnose its presence before operation, but in some cases a severe and continued headache may lead us to suspect an epidural abscess. Such abscesses are, however, a part of rather than a complication of a mastoid infection, and in either case if the operation is performed before the infection has extended through the sinus or dura the recovery is uneventful.

As I have stated above, we may have an arthritis, pyelitis, tuberculosis, or almost any other infection with a case of mastoiditis, but the ones above enumerated are the real complications and those found in a very large percentage of cases.

167 West Seventy-first Street.

A DIFFERENTIAL HISTORY FORM FOR ENLARGEMENTS OF THE THYROID GLAND.

By FREDERICK CHRISTOPHER, S.B., M.D.,

EVANSTON, ILL.

RECENTLY HOUSE SURGEON, SECOND SURGICAL DIVISION, NEW YORK HOSPITAL.

THE importance of a careful and complete history in making a correct diagnosis of enlargements of the thyroid has frequently been emphasized. The following is a questionaire intended to serve as a guide in taking histories of cases with thyroid enlargements and in it an effort is made to suggest such inquiries as will help to differentiate the various possible etiological factors.

My former chief, Dr. Eugene H. Pool, has said: "It is of vital importance that we should know what symptoms are due to hyperthyroidism, hypothyroidism, and dysthyroidism, and how and to what extent other glands modify these symptoms" (*Johnson's Operative Therapeutics*). Study of cases of thyroid enlargements will throw but little light on these points unless complete histories in which negative as well as positive findings were noted have been made. Again the history may be of prime importance in helping to decide the question of operation or non-operation, as in incipient Graves' disease *vs.* parenchymatous goiter in anemic girls. It may bring out contraindications to operation not revealed by the physical examination.

The following history form is intended as a guide particularly for clinical clerks and internes in large hospitals, and it is hoped that printed forms similar to this one and with appropriate spaces for the answers to the questions might be incorporated into patients' bedside charts.

It may be objected that in using a form of this kind the diagnosis of "enlargement of the thyroid" must be made before the history is taken. This objection is very likely to be overruled when it is considered that swellings in the neck which rise and fall during deglutition are enlargements of the thyroid with but very few exceptions, as (*a*) A swelling not thyroid in origin, but lying in front of it, such as a subhyoid bursa or sebaceous cyst, and (*b*) a syphilitic perichondritis of the thyroid cartilage. A thyroid swelling, however, if fixed by inflammation or malignant growth, may not present this sign.

In order to construct a differential history form, we have considered the points in the history to which attention should be directed in (*a*) the different forms of thyroid enlargement, (*b*) dysfunction of other glands of internal secretion, and (*c*) diseases and conditions contraindicatory to strumectomy. We have then endeavored to assemble all these points into one composite chart.

I. *Exophthalmic Goiter.*

A. Present Illness—

(*a*) Onset—when, with what symptoms, location, and size of swelling.

(*b*) Course—rate of growth, change of position if any in growth.

(*c*) Subjective Symptoms—

1. Pain in lump—when, duration, character, etc. (Sometimes in Graves' disease superimposed on old goiter.)

2. Palpitation, tachycardia, and arrhythmia-relation to exertion, excitement, when first noticed, etc.

3. Nervousness, irritability over trifling causes, excitability, restlessness, depression, apprehension, worry, exaltation, psychoses, globus, vertigo, insomnia, faintness, hysteria. Tell specific instances, give dates, causes of worry and of irritability, domestic relations, ability to do painstaking work (sewing, etc.).

4. Muscular weakness (when and how noticed) "giving away of legs," difficulty in ascending stairs.

5. Alterations in organs of sense—touch, temperature, feelings of increased warmth, hearing, smell, eyesight (transitory veil sensations before the eyes), taste.

6. Alimentary symptoms—appetite, now and before operation, quantities of food consumed, thirst, vomiting, diarrhea (occurrence in paroxysms?), abdominal pain, constipation.

7. Dyspnea: (*a*) related to mechanical pressure of enlarged thyroid; (*b*) dependent on diminished expansion due to muscular weakness.

8. Cough, hoarseness, aphonia.

9. Sexual changes: (*a*) impotence; (*b*) alterations in menstruation since outset of disease—amount of blood, pain; duration and frequency of menses, new subjective sensations during menstruation, especially as related to thyroid.

(*d*) Objective Symptoms—

1. Protrusion of eyes, when first noticed, rate of increase, variations, etc.

2. Hemorrhages from nose, lungs, stomach, or skin.

3. Tremor of hands—when first noticed, character, causal relations if any.

4. Changes in the skin—Elevated temperature, increased readiness to diaphoresis, dryness (suggestive of hypothyroidism), color (pallor, flushes, pigmentation, anomalies, pruritus, edema, (circumscribed and of extremities), alopecia.

5. Other glandular enlargements in neck.

6. Swelling in region of sternum suggesting persistent and enlarged thymus.

7. Loss of weight—details.

8. Fever as measured by thermometer.

9. Ptosis or unilateral miosis.

B. Past History—

1. Localities lived in and how long in each place.

2. Shock, fright, or worry previous to outset of disease—name incidents.
3. Colds, tonsilitis, sinusitis, pyorrhea, alveolar abscess; other acute infections—lues, rheumatic fever, measles, whooping cough, mumps, malaria, tuberculosis.
4. Iodism.
5. Neurasthenia.
6. History of respiratory system, including night sweats.
7. History of circulatory and digestive systems.
8. History of genito-urinary system, including venereal infections, number and character of pregnancies.
9. Habits of life—drink, character of work, etc.

C. Menstrual History—
Outset of menses, regularity, intervals between periods, duration of each period, blood lost (number of changes per diem), pain (when, where, severity, etc.), mental condition at menses. Increase or decrease in flow since onset of goitre symptoms.

D. Family History—
Incidence of Graves' disease in relatives; health of relatives.

II. *Hypothyroidism.*
Age of onset, rate of growth, objective changes in size of thyroid, changes in skin (swelling of eyelids, dryness, yellowness, flush in malar region, thickening (where, face?), scales, hair coarse, dry, and falling out).
Mental changes (loss of memory, indecision, listlessness, suspiciousness, hallucination), alterations of voice (slow, muffled), changes in gait, difficulty in walking, stiffness, headaches, neuralgias, lacrimation, deafness, tinnitus, anomalies of taste, diminution in sense of touch, bradycardia, anorexia, indigestion, absence of thirst, constipation, diarrhea, irregularity of menses, leucorrhea.
Localities lived in, previous operations on neck, alcoholism, tuberculosis, acute infections, as typhoid, influenza, pneumonia, cholera, syphilis, malnutrition, malaria, gout. Lues in parents, other instances of this disease, of goitre, or of exophthalmic goiter in the family.

III. *Thyroiditis.*
Duration of swelling, rate of growth of swelling, pain (radiating to ears, occipital region, teeth?), tenderness, fever, chill, malaise, dyspnea, hoarseness, dysphagia.
History of trauma, or of typhoid, smallpox, scarlet fever, measles, diphtheria, cholera, influenza, acute rheumatic fever, various infections of nose, pharynx, and tonsils, erysipelas, puerperal fever, malaria, pneumonia, alcoholism, phosphorus and iodine poisoning.

IV. *Lues.*
Time of onset in known case of lues (generally in secondary incubation stage, or in period of secondary rash), history of syphilis, absence of pain, or hardness in swelling.

V. *Tuberculosis.*
Situation and character of swelling—mode and rate of growth (rapid nodular growth—may be external or internal), exact inquiry into history of patient's respiratory system and family history, environment, character of work, etc.

VI. *Echinococcus.*
History of exposure, lesions elsewhere, urticaria, dyspnea, suppuration, and necrosis.

VII. *Malignant tumors (carcinoma, sarcoma).*
Onset (early symptoms resemble those of goitre or strumitis), time at which skin becomes fixed to tumor, dyspnea, dysphagia, hoarseness, exophthalmos, miosis, loss of pupil reaction, tachycardia, paralysis of arm, hemorrhages from larynx and trachea.

VIII. *Goiter (cystic and adenomatous).*
Onset, rate of growth, variations in rate of growth, symptoms of pressure on (*a*) trachea, (*b*) laryngeal nerves, dysphagia, palpitation ("goiter heart"), menstrual history in relation to goiter.
Localities lived in and how long in each place, history of congestion, either emotional or mechanical, trauma, infection.

IX. *General Hypertrophy.*
Similar to goiter, except for symmetrical growth.

X. *Dysfunction of other glands of internal secretion.*
A. Pituitary Body—
Headache, irritable temper, moroseness, pains in joints, disturbances of vision, loss of memory, slowness of mental processes numbness, and tingling of extremities, increased appetite and thirst, constipation, polyuria, dyspepsia, amenorrhea, impotence, increased growth, particularly of extrmities, gain in weight, changes in voice (deeper), speech slower, strength or weakness of all or of individual muscles, bursts of anger, insanity.

B. Adrenals—
Gradual falling off of general health, asthenia, anorexia, loss of weight, pain and tenderness in region of stomach, vomiting, and digestive disturbances, bronzed color of skin, tendency to fatigue from mental exertion, apathy, depression, insomnia, loss of memory.

C. Pancreas—
While pancreatic insufficiency supposedly directly affects the thyroid (and the adrenals as well) it would seem impossible to get a history of subjective symptoms in a case of pancreatic insufficiency.

D. Gonads—
(*a*) Male—impotence, disturbances of secondary sex characteristics, excessive skeletal growth.
(*b*) Female—disturbances of secondary sex characteristics and of menstruation.

E. Thymus—
No definite history of symptoms attributable to a persistent thymus or to a status thymicolymphaticus may be obtained. There may, however, be a history of increased prominence over the upper part of the sternum of "thymic asthma" or of goiter.

XI. *Symptoms which might show disease or conditions contraindicatory to operation.*
(*a*) Evidences of heart disease—dyspnea on exertion (see goiter), palpitation, edema, etc.
(*b*) Evidences of kidney disease—edema, etc.
(*c*) Evidences of (*α*) gastric crises, (*β*) acute delirium, (*γ*) diarrhea, (*δ*) ascites.
(*d*) Myxedema (see above).
(*e*) Status thymicolymphaticus — no definite symptoms available.

In the following form an effort has been made to bring these groupings together. Where mere mention of the symptom is made, it is taken for granted that the interrogator will ask first if there is a history of such symptom and, if there is, when the symptom first was noticed, its intensity, remissions, exact description, etc.

DIFFERENTIAL HISTORY FORM FOR ENLARGEMENTS OF THE THYROID GLAND.

A. *Chief Complaint* (in patient's own words).
B. *Present Illness* (including all events since first appearance of symptoms attributable to the thyroid).
(*a*) *Onset*—Symptom first noticed and when. Location and size of swelling when first noticed.
(*b*) *General Course*—Rate of growth, changes in position of lump, remissions, formation of nodes, fixation of skin to swelling, etc.
(*a*) *Subjective Symptoms*—
1. General: Gradual failing of general health, feeling of weakness, malaise, chill, fever, headaches.
2. Local pain (radiations) and tenderness in swelling, suppuration, necrosis.

3. Circulatory system; palpitation, tachycardia, arrhythymia, with relation to physical exertion and emotion, bradycardia, ascites.
4. Respiratory system; dyspnea on exertion, cough, hoarseness, aphonia, asthma.
5. Digestive system; variations in appetite, in thirst, dysphagia, indigestion, vomiting, constipation, diarrhea (in paroxysms?), abdominal pain or tenderness.
6. Nervous system and mental conditions: Irritability over trifling causes, excitability, restlessness, depression, apathy, apprehension, worry, exaltation, psychoses, globus, vertigo, insomnia, faintness, hysteria, loss of memory, indecision, hallucinations, moroseness, bursts of anger, readiness of fatigue after mental exertion.
6. Organs of special sense: Alterations of temperature, touch, or taste perception, disturbances of hearing (tinnitus, etc.), variation in sense of smell, of sight (transitory veil sensations before the eyes, etc.)
7. Muscular-locomotory system: Muscular weakness (general or individual muscles), pains in joints, numbness of extremities, paralyses, changes in gait, stiffness.
8. Genito-urinary system: polyuria, impotence, alterations in secondary sex characteristics, changes in menstruation since onset of disease, especially changes in the swelling during menstruation, leucorrhea.

(β) *Objective Symptoms*—
1. Changes in skin: Variations in surface temperature, in diaphoresis, dryness, presence of scales, color (pale, flushes, yellow pigmentation, bronzing local changes), edema, or swelling (circumscribed or general), thickening, allopecia, coarseness and brittleness of the hair, pruritis, urticaria.
2. Changes in appearance of eyes (protrusion, miosis, loss of pupillary reaction).
3. Changes in speech (rate and pitch).
4. Hemorrhages from nose, larynx, lungs, stomach, skin.
5. Tremor (interference with work).
6. Swellings elsewhere (neck or over sternum), liver.
7. Variations in weight and skeletal growth.
8. Fever as measured by thermometer.
9. Insanity.

C. *Past History.* (Events previous to onset of first symptom.)
1. Localities lived in and how long in each place.
2. History of shock, fright, worry, neurasthenia.
3. History of local trauma or congestion.
4. Previous operation on neck.
5. History of typhoid, smallpox, scarlet fever, measles, diphtheria, cholera, influenza, acute rheumatic fever, various infections of nose, sinuses, pharynx, teeth, and tonsils, erysipelas, puerperal fever, malaria, pneumonia, whooping-cough, mumps, tuberculosis, syphilis (at what stage of disease did enlargement appear?), malnutrition, gout.
6. History of alcoholism, iodism, or phosphorus poisoning.
7. Exact inquiry into respiratory history, including night sweats.
8. History of circulatory, digestive, and genito-urinary systems, including venereal infection, and number and character of pregnancies.
9. Habits of life and character of work.

D. *Menstrual History.*
Onset, regularity, intervals between, duration of each period, blood lost (number of changes), pain (when and where), mental condition at menses.

E. *Family History.*
Age of parents; if dead, age and cause of death. Incidence of enlargements of thyroid, tuberculosis, syphilis, chronic heart or kidney disease in the family, health of brothers and sisters.

934 Michigan Avenue.

ACUTE DIABETES MELLITUS.

By EDWARD O. ELMER, M.D.,
HARTFORD, CONN.

THE following is a report of a case of acute diabetes mellitus, which to me is most unusual, and seems worthy of record:

S. K., aged 10 years; only child. The father, at 37, is physically well, but of unstable mental makeup, being thought by some to be demented. His father was demented and committed suicide a few years ago. The mother comes from a decidedly nervous family; is melancholic and always looking for trouble. A great aunt has had diabetes for years. The child has always been healthy with the exception of chickenpox and whooping-cough. She has always been very fat. She first complained on October 24, 1917, of being tired and of her legs aching; her appetite was poor and she was somewhat constipated. The following morning she said that she was still tired and did not go to school. I saw her that morning at 11 o'clock and found her dressed and about the house. Temp. 98°, pulse 120, respirations 30. No headache or cough; was chilly. She was given calomel, followed by a seidlitz powder; was also put on a light diet and advised to keep quiet. She had a sleepy night, only awakening to urinate, which was often. I saw her again at 8 o'clock the next morning, the 26th, and found her dyspneic and very somnolent; temp. 97°, pulse 135, and resp. 40. Tongue dry, sweetish odor to the breath. She said she was tired, but had no pain. Had voided seven pints of pale acid urine during the last 18 hours; sp. gr. 1020, containing about 16 grains of sugar to the ounce. She was put upon sodium bicarbonate, 1 dram in water every 4 hours, by the mouth, and a tablespoonful in 6 ounces warm water by the rectum, following a soap enema every 12 hours. Barley water, a thin oatmeal gruel, and buttermilk were fed her in small amounts. She continued getting sleepier during the day and evening and at midnight went into coma, dying the next morning (October 27) at 6 o'clock.

In searching about for a possible cause for this condition, I obtained this following bit of information: While this girl was returning from school on October 23, the day before she was taken ill, she, in company with several other children, was chased by an older boy, whose face was covered with a mask. This badly frightened her, so much so that she was some time in quieting down; and being very fat and the distance long, was thoroughly fagged upon her arrival home. Nothing else in the way of a contributing cause can be found.

805 Park Street.

Endocrine Organs of Dementia Precox.—Kojima finds that there is a tendency to thyroid hypofunction in the male as opposed to one of thyroid hyperfunction in the female precox case. In the parathyroid differences are also in evidence. In both sexes there are parallel differences in sexual glands—slight spermatogenesis and early involutions of the ovaries.—*Proceedings Royal Society of Medicine.*

Tympanismus Vagotonicus.—Ortner, appropos of a recently published case of this newly isolated syndrome recalls that 20 years ago he drew attention to a case of intermittent meteorism with bradycardia. It was found that the left vagus had been compressed in the mediastinum by a tuberculous gland. Patient was in advanced phthisis.—*Nederlandseh Tijdschrift voor Geneeskunde.*

Diagnosis of Smallpox.—According to Schreiber varioloid is but slightly typical and can easily be confounded with varicella. He would therefore practise inoculation of the rabbit's cornea in doubtful cases. But while a positive result speaks for itself a negative one does not exclude varioloid. In some cases we can do no better than isolate the varicella case.—*Correspondenz-Blatt für Schweizer Aerzte.*

Military Medicine.

THE STANDARD FOR EXEMPTION OF TUBERCULOUS RECRUITS FROM THE NATIONAL ARMY.*

By M. J. FINE, M.D.,

NEWARK, N. J.

ACTING CHIEF OF BUREAU OF TUBERCULOSIS NEWARK BOARD OF HEALTH; EXAMINING PHYSICIAN FOR ESSEX COUNTY MOUNTAIN SANATORIUM, VERONA, N. J.; CHIEF OF TUBERCULOSIS CLINIC NEWARK BETH ISRAEL HOSPITAL.

THE need of standardizing the diagnosis of tuberculosis for use in the examination of recruits for the National Army is evident; there is, however, tremendous difference of opinion among physicians and those possessing special knowledge on the subject, as to what constitutes clinical tuberculosis; it is, therefore, no easy task to devise a definite standard.

A man who is unwilling to serve his country would be glad and earnestly strive to exaggerate his symptoms, while, on the other hand, the man anxious to serve would endeavor to conceal evidence of his disease. The statement of the recruit should not carry too much weight, but instead I think it would be a good policy to require that the local Board of Health supply the history of reported cases to the recruiting officers. Even now our tuberculosis department is rendering aid to eradicate tuberculosis from the National Army by following up cases of the disease as soon as they are announced by the press as having been accepted for the army. Up to the present we have been instrumental in having 30 cases of tuberculosis recognized, and about one-half of these have been sent home as unfit for service in the army, even though at the time they were not afflicted with any manifest symptoms of the disease.

Dr. Barber, Medical Inspector U. S. Navy, advocates the rejecting of all men who have only a tendency toward tuberculosis, and he proves statistically that almost all the men in the Navy suffering from tuberculosis who are in the Government Sanatorium are cases of less than one year in the service, and that the recruiting officers could have kept these men out of the Navy.

Neither is a negative sputum reliable. By accepting men, who, although suspicious of tuberculosis, have a negative sputum, we are increasing the number of active cases in the Army and lessening the chances of recovery for the man. We could prevent all this by excluding any suspicious case, or if not entirely rejecting him keep him under observation for at least one month during which time an absolutely correct diagnosis could be made.

A valuable aid in the prompt detection of tuberculosis cases would be the search for physical signs, sputum examination, and *x*-ray diagnosis. To accept a man with any positive sign or tendency to tuberculosis for service in the Army is *not* a patriotic act and when this is done knowingly it could almost be considered traitorous, as it endangers the health of the Army as a whole. Such men are useless for furthering the common cause, and only add to its burdens.

*Read before the Joint Tuberculosis Conference, Jersey City, November 9, 1917.

When we consider the protracted nature of the disease, the expense of treatment, the claim for government pensions for such men, we can easily realize what a heavy liability the government assumes in accepting men who have a tuberculous tendency which the hardships incident and inseparable from Army life will inevitably develop into active cases of the disease. In normal civil life such individuals might attain an advanced age and even be in a position to serve their country in some of the less arduous pursuits.

The assertion so frequently made that "roughing it in the Army," living in the open air, *et cetera*, has benefited and cured tuberculosis does not hold true as far as Army life is concerned, and is not borne out by the facts collected during the present war, when we consider the enormous number of cases of tuberculosis that developed on the various battle fronts, notably in France. Tuberculosis, in the final analysis, with regard to the Army, only helps to swell the pension lists and shows nothing in the line of service performed to counterbalance the liability it imposes upon the government. If further arguments are needed one has but to note the character of the life on the battle fronts. The soldier has to live under rather unhygienic conditions, subject to overexertion, loss of sleep, inadequate food, besides the emotional stress and shock which are his daily experience. In fact, he must do all things that a tuberculous patient should not. Under such circumstances the incipient case or the one with healed lesions rapidly progress to an aggravated and active case.

Schroeder points out that nearly all cases of tuberculosis in the German army had at one time suffered from the disease, but that it had healed and the men were sound when accepted for the army. Life at the front, however, lighted up these cases anew, by means of the altered and unusual living conditions.

Maragliano advocates rejection from the Italian army of all cases whether active or latent. He points out particularly that foci of tubercle bacilli may, and do remain, circumscribed as long as the resistive forces of the organism are able to oppose to them an adequate defense, but remarks that no man can guarantee that a tuberculous recruit with latent infection will have sufficient resistive power to bear the depressing incidents of life in the army under actual fighting conditions.

The final conclusions to be drawn from this article and which I wish to strongly advocate may be summed up as follows:

1. The examination of the chests of all recruits should be made by competent men who are doing special work in that line, and are able to diagnose tuberculosis in the incipient stage.

2. Active cases should be *ipso facto* and unconditionally rejected for army service.

3. Certain cases might be accepted as "good risks," but that these should be under observation for a period of one month at least, during which time all diagnostic resources should be repeatedly applied.

4. When latent tuberculosis is positively demonstrated a rejection should also be made.

5. In a suspicious case, if after a thorough ex-

amination a positive diagnosis of tuberculosis cannot be demonstrated, the recruit should be employed in the lighter tasks of army work and never subjected to the conditions which prevail on the active battle fronts.

It would appear at this time that the Army can very well dispense with the service of the healed tuberculous soldier, or of the soldier in the incipient stage of the disease, for the reason that we have not yet exhausted our available supply of healthy material. We can, however, imagine a time in the period of the war where a call will have to be made upon every man below the age of fifty, good, bad, or indifferent. Should this unforeseen time ever come, then the necessity of using the tuberculous soldier will become evident. Even then it would be very advisable to use such obviously dangerous material in special tasks or units confined to specific and separate divisions.

362 Clinton Avenue.

Treatment of a Series of Recently Inflicted War Wounds with Flavine.—Hamilton Drummond and J. W. McNee offered a report to the Medical Research Committee on this series of treatments, and Anthony Bowlby prefaced it with the following facts: In the first place it appears that flavine does not sterilize recent wounds, and that various bacteria grow freely in wounds treated with it. Secondly, it appears to cause a very superficial necrosis, and the formation of a fibrous membrane, if applied in the strength of 1 in 1000. In spite of the bacteria there is a notable absence of inflammation and of septic infections, and in the cases observed no bad examples of gas gangrene were produced, although anaerobic organisms were present in many wounds in large numbers. Also, healing by granulation is very slow, and the growth of granulations is evidently checked by the presence of flavine. As far as the present series of operations goes, it does not bear out some of the claims made for flavine as a bactericidal agent or as to its harmlessness to the tissue cells. But it appears to be a useful application in the form of gauze soaked in the solution when used as a first dressing to large open wounds, and it seems to limit the power for harm of the pathogenic organisms and to prevent the inflammation of the tissues which is usually caused by bacterial invasion.

Drummond and McNee employed a strength of 1 in 1000 of flavine for the first dressing and a solution of 1 in 5000 for all subsequent applications. In some cases also, where the Carrel method of irrigation was being used, the strength of the solution was reduced to 1 in 10,000. In this test a series of 70 cases were under treatment, but as many of the men had simple injuries, the series comprises over 120 wounds. The vast majority of the wounds were caused by the fragments of shells or bombs, only about eight injuries from rifle or machine gun bullets being encountered while the test was in progress.

They divided the wounds into three classes: (1) Flesh wounds, including all injuries to soft parts without damage to bone; (2) compound fractures; (3) miscellaneous wounds of special parts—abdomen, chest, head, and joints. In the surgical measures adopted consideration was given to the type of injury met with. They consider that long incisions, with free excision of damaged muscle and fascia, must be regarded as a cardinal part of all operative treatment in recent wounds, no matter what subsequent methods are employed.

After this preliminary surgical treatment the wounds treated with flavine were dealt with in the following ways: Primary suture—this method was employed in 30 cases, all being wounds of the soft parts alone. In the majority of these, the damaged muscle removed at operation was examined bacteriologically and shown to be infected. Fragments of cloth, and dirt, were also commonly removed from the track of the wound. (2) Drainage by tube or gauze strip, followed by secondary suture—this was carried out in 10 cases. (3) The Carrel method of intermittent irrigation—The perforated tubes were irrigated with the flavine solution every four or six hours. This method was chiefly employed for compound fractures and deep or extensive muscle injuries. (4) Gauze packing in open wounds—This was found very useful in the treatment of many extensive wounds where the Carrel method was not readily applicable; for instance, in certain types of compound fracture and in amputation stumps where complete closure was impossible.

The gauze packing, soaked in flavine, could be left *in situ* for several days without changing the dressing.

From these tests with flavine Drummond and McNee draw the following conclusions: (1) Flavine appears to have many advantages as a *primary* treatment of recent war wounds. Among the advantages are: (*a*) The absence of all toxicity, even in large wounds. (*b*) The prevention of suppuration and of spreading sepsis, as brought out in our series of test cases. (*c*) The primary dressing need not be changed for two or three days, and is then easily and painlessly removed. This may be of great advantage during severe fighting where rapid evacuation of wounded from front to base is required without unnecessary dressing of the wounds. (*d*) The wounds are not inflamed or painful, and the surrounding skin is never irritated. (2) Emphasis must be laid on the fact that excision of damaged tissue and mechanical cleaning of the wound are necessary preliminaries to the use of flavine. (3) Flavine cannot be classed as a success in the treatment of the *later stages* of war wounds. The wounds tend to assume a stagnant condition, during which the processes of repair are almost in abeyance. After a few days, when the danger of gas gangrene and of spreading sepsis have to a great extent passed off, flavine should be stopped and another treatment adopted. (4) In the majority of cases war wounds are not rendered bacteriologically sterile even by the prolonged use of flavine. (5) Test-tube experiments carried out with organisms isolated from actual wounds bear out the strong antiseptic properties of flavine, and their enhancement in the presence of serum. Coliform bacilli, which are a common infection in the later stages of wounds, are much more resistant to the action

of the antiseptic in test-tube experiments than any of the other types of organism examined in this way.—*The Lancet*, October 20, 1917.

Report on Wound Treatment by Brilliant Green Paste.—Rendle Short, J. S. Arkle, and C. King comment on the difficulties presented in the treatment of wounds, both by the Carrel method and the "Bipp" treatment of Rutherford Morison. The Carrel technique, according to them, needs much attention, and when the patient is traveling this may not always be secured. The soaked dressings need daily changing. The tubes are liable to come out and it may need an anesthetic to replace them. While bipp is much less trouble they consider that it presents drawbacks of another sort. It is occasionally poisonous, either from the bismuth or the iodoform, or both. It may delay healing; when the stitches are taken out after secondary suture the wound may fly open. It leaves a residue in the tissues, opaque to the *x*-rays, which may give rise to trouble later.

They have therefore been employing for some months the paste introduced by Captain Hey, consisting of brilliant green, boric acid, French chalk, and liquid paraffin. They claim for it the following advantages: (1) It is non-poisonous. The symptoms of boric acid poisoning—persistent vomiting and a peculiar rash—should be watched for, but although in many cases they have used very large quantities of the paste they have seen no ill effect result from its use. (2) It is painless. (3) In the great majority of cases it almost completely sterilizes the wound in three days, so that secondary suture can be performed even in large wounds complicated by bony injury. Small, completely excised wounds can be primarily sutured. (4) The wound need only be dressed about once in four days. (5) No permanent residue is left to interfere with immediate healing.

Before applying the paste the wound must be thoroughly opened up and excised, and any foreign bodies removed. If this is not possible—for example, in a shocked patient with multiple wounds or with a long deep track exposing important structures—they prefer to use Carrel's method. The paste is only to be applied if it can be applied completely. The wound ought to be dry and not bleeding, but a certain amount of oozing can be checked by a gauze plug (preferably paraffin gauze, which is easier to remove). The paste should be rubbed in thoroughly. It soon washes off the skin or gloves.

By this method they have been able with fair consistency to obtain healing within a fortnight of cases of compound fracture even when complicated by joint injury, big buttock wounds and deep muscle wounds. They have excised an elbow-joint full of pus, and obtained primary healing in a fortnight.

The usual procedure is to stain the track of the missile, excise and paste it, and either leave it open or insert a few central sutures. On the third or fourth day a smear of the deepest part of the wound is taken. If *B. perfringens* is absent, as is almost invariably the case, and the organisms are not more than six to the field, they completely close the wound by secondary suture. Often the wound shows no organisms at all. They consider that it is easier to count the organisms with this method than when bipp has been used. A little redness and swelling on the fourth day can usually be remedied completely by hot fomentations. They found that Hey's method of staining the wound by injecting through a Carrel tube with a 1 in 200 watery solution of brilliant green was a very valuable aid to complete excision.

In ten cases the method failed of complete success. Of these, four were hopeless from the beginning. One of them was an attempt to save a leg in which it was afterward found that both tibial arteries were divided in addition to the presence of a big muscular wound and a smashed tibia and fibula. The excision was inadequate, owing to shock and consequent hurry, and it became necessary to amputate for gas gangrene. In another, in which death followed within forty-eight hours from gas gangrene, the bad condition of the patient did not permit of a prolonged search for the foreign body, while the appearance of the wound at the time of operation suggested early gas gangrene, which had already spread too far for complete excision. Fifty-four other cases in which brilliant green was used were successful, while there were ten in which for various reasons the results were either relatively or wholly unsuccessful.—*British Medical Journal*, October 20, 1917.

Large Military Hospital for Staten Island.—Surgeon General Gorgas has announced the selection of Fox Hills, Staten Island, N. Y., as the site for a military receiving hospital from which wounded American soldiers will be distributed to the reconstruction and rehabilitation hospitals which it is planned to establish in various parts of the United States. The Staten Island hospital will have a capacity of from 1500 to 2500 beds, and will be situated near enough to Quarantine Station to make possible the transfer of the wounded with the minimum of delay. At this institution the wounded soldiers will be given a thorough mental and physical examination by medical officers, and they will then be transferred to a general or special treatment hospital. So far as possible soldiers will be sent to general or special hospitals near their own homes. As the additional sites for rehabilitation hospitals are decided upon they will be announced by the Surgeon General.

Camp Funston Men Forbidden to Mingle with Civilians.—Owing to the existence of spinal meningitis and other infectious diseases among the troops at Camp Funston, orders have been issued forbidding the men and officers of the 89th Division to visit theaters, church sociables, or other public gatherings, in Junction City, Army City, Ogden, or Manhattan.

Pneumonia and Measles in Army Camps.—The report of the Surgeon General of the Army for the week ending November 23, shows that there were 157 deaths in the National Guard and National Army camps where are quartered 801,072 men. This is an increase of 61 deaths over the previous week. There were 116 deaths from pneumonia and 9 from cerebrospinal meningitis. In the National Guard camps there were 4080 new

cases of measles reported as against 901 in the National Army camps. At Camp Upton, Yaphank, L. I., there are no cases of measles, while at Camp Jackson, Columbia, S. C., there were 523 cases reported during the week of November 23. The greatest increase in measles was reported from Camp Bowie, Fort Worth, Texas, where there were 1038 new cases. At Camp Sevier, Greenville, S. C., 802 new cases were reported. No measles was reported from Camp Wadsworth, Spartansburg, S. C. In the National Guard of New York there has been no measles, but there are 350 cases of sickness. At Camp McClellan, Anniston, Ala., there are 19 cases of measles and 371 cases of sickness. At Camp Dix, Wrightstown, N. Y., measles do not exist, but there are 516 cases of sickness. At Camp Wheeler, Macon, Ga., 1402 cases of sickness were reported, of which 150 were pneumonia and 49 measles. Surgeon General Gorgas has recently made an investigation of this camp and his suggestion that only five men be permitted to occupy a tent instead of nine as at present will be carried out; this, it is believed, will improve health conditions. It has been rumored that a considerable number of cases of pneumonia from the camps in the vicinity of New York are being cared for in New York hospitals, Mount Sinai Hospital, the New York Polyclinic, St. Francis, St. Luke's, the Presbyterian, Metropolitan, and City hospitals, have expressed a willingness to care for a certain number of cases from the camps.

The War Service Committee of the American Hospital Association held a meeting in New York City on November 21. This is a national committee which has been instructed by the American Hospital Association to inform itself of all military facts and requirements in which hospitals may be concerned, to be ready to consult with military authorities thereto, and to assist wherever and whenever hospital service may be of value to the country. The committee has established headquarters in Washington. The chairman of this committee, Dr. S. S. Goldwater, has issued a statement which the committee has authorized him to present to the military authorities through the General Medical Board of the Council of National Defense. This statement regrets the apparent policy of the army to ignore existing hospital facilities in its preparation for the care of invalided men and expresses the opinion that it would be wiser to formulate a program based upon the principle that existing institutions, including hospitals and sanatoria, should be utilized wherever and whenever they are capable of rendering the required service. It considers the unnecessary duplication of hospital plant and organization at a time when the nation should husband its resources deplorable. The ideas of the War Service Committee are practically those of the British Ministry of Pensions, which states that it has no intention of setting up in various parts of the country institutions which would compete with established voluntary hospitals. Quite generally additional accommodations when required were provided by enlarging existing institutions. In order to facilitate cooperation between the army and civilian hospitals, the committee suggests the organization of an Auxiliary Medical Corps for Home Service. This corps should be composed of physicians and surgeons who are ineligible for active military duty, and should be made up in the first instance of men holding hospital appointments. The committee maintains that the efficiency of hospitals and the adequate preparation of recent graduates in medicine for clinical practice, not only among the civilian population but in the army, depends in large part upon the maintenance by civilian hospitals of an adequate system of clinical training. In the opinion of the committee it is inadvisable for hospitals having a graduated interne service of 18, 21, or 24 months' duration to abandon such service, in order to substitute an ungraded or improperly graded service of only 12 months' duration.

Base Hospital No. 30 Mobilized.—Base Hospital No. 30, organized in the University of California Medical Department, has been ordered to mobilize for training of enlisted personnel at Fort Mason, San Francisco, Cal. For this purpose it has been placed under command of Col. Elmer A. Dean. Most of the officers of the organization have already had military training and at the present time are in active service in various parts of the country. Those ordered for immediate mobilization with the unit are: Major Eugene S. Kilgore, Director and Chief of Medicine; Captains Jule B. Frankenheimer, Louis P. Howe, and Arthur L. Fisher, and Lieutenants Malcolm Goddard, Hiram E. Miller, and John M. Rehfisch. The remainder of the official personnel are to be assembled when the organization is ready for foreign service. These include: Drs. Elbridge J. Best, Ernest H. Falconer, Arthur C. Gibson, C. R. Giles, Charles M. Richards, Howard E. Ruggles, Hudson Smythe, Charles L. Tranter, Herbert S. Thomson, William W. Washburn, Alanson Weeks, Nathan P. Wood, J. Homer Woolsey, Harold W. Wright.

Army Surgeons for Roumania.—The Surgeon-General of the army, with the authority of the Secretary of War, has organized a body of 100 army surgeons for service in the hospitals of Roumania. This is the first detachment to be sent for service abroad other than with the French, British, or American forces. Col. Walter D. McCaw of the regular army will have charge of the unit, which will report to the American minister at Jassy, Roumania.

Red Cross Ships Christmas Gifts.—The American Red Cross has assembled 200,000 Christmas presents, making 200 tons of goods, for shipment to American troops abroad. The Red Cross announces that the full overseas allotment has been provided and that no soldier or sailor abroad will be left without a Red Cross remembrance. The Red Cross intends to erect a Christmas tree at each of the cantonments in this country and to provide other forms of Christmas entertainment at the camps.

Ambulance Section for Italy.—The American Red Cross has started a section of twenty-five cars loaded with medical supplies, clothing, and food for Italy. Additional ambulance drivers are to depart soon.

Supplies Reach Roumania.—The American Red Cross relief train arrived at Jassy, Roumania, on November 18; it included fifty-five carloads of hospital supplies and foodstuffs from America.

THE NATURE AND CONTROL OF HEMORRHAGE.

ASIDE from infection, hemorrhage is probably the most common and most feared eventuality which the surgeon must anticipate and with which he must deal. The hemorrhage that is the result of wounded or unligated blood-vessels is easily disposed of along purely surgical lines. But the hemorrhage that is the result of oozing from very small and unligatible vessels in inaccessible parts of the body, as, for example, in nasal operations, is dependent for its stoppage upon the clotting qualities of the blood. This ability for a shortened clotting time is lost in such constitutional diseases as hemophilia, in jaundiced conditions, in adrenal disease, in unaccounted low coagulability of the blood, and in arteriosclerosis and high blood pressure. These conditions are nonsurgical, but unless they are taken into consideration by the surgeon even very slight operations may have a fatal outcome. When any of these constitutional conditions are diagnosed only the most urgent operations must be performed until, at least, the coagulation time of the blood can be definitely shortened. Moreover, even in the absence of these conditions some people have a tendency to bleed more profusely than others. In the same way some tissues bleed more than others. A clearer understanding of the clotting mechanism of the blood would undoubtedly place this subject on a more definite basis. According to Morawitz all tissues of the body, especially the blood platelets, contain a substance called thrombokinase, while normal blood contains as constant elements such substances as prothrombin, antithrombin, calcium salts, and fibrinogen. When any of the tissues or the formed elements of the blood are injured the thrombokinase combines with the calcium salts and with prothrombin to produce a new substance called thrombin which, together with fibrinogen forms the fibrin or clot, necessary in the prevention of continued hemorrhage. On the other hand, Bordet and LeLange maintain that thrombin is formed as a result of the reaction between cytozyme and serozyme in the presence of calcium salts. Cytozyme is found in the blood platelets, leucocytes, and tissue juices while serozyme is found in blood serum. Antithrombin is necessary to prevent the formation of clot in the blood stream, but acts also to prevent it on the outside except for the presence of the thrombin elements. At any rate the balance between the clotting and the anticlotting elements of the blood is very delicately maintained and any injury to the tissue releases a substance called thromboplastin which binds the antithrombin and permits the formation of fibrin by the elements so purposed. Other workers have advanced modified theories on this subject, but they all savor of the principle of antagonistic elements in the blood tending to keep a balance between clotting and nonclotting until the continuity of the tissues is broken.

It is maintained that antithrombin is elaborated in the liver, yet venous blood taken from the liver does not contain any more of it than venous blood taken from other places. When, however, there is stasis in other vessels the liver blood is the only blood that shows an increase in the antithrombin. The increase in the sugar content of the blood increases its coagulability. The injection of adrenalin into the blood circulation acts likewise, but in this case the action is indirect, due, in all likelihood, to the vasoconstriction induced and the discharge of internal secretion and other tissue juices into the blood (Weinstein, *The Laryngoscope*, March, 1917). More specifically, it is believed that adrenalin stimulates the liver to discharge some substance into the blood which acts to increase coagulability. In any event, the coagulation factors or elements may be localized to the abdominal contents, and their exclusion increases the clotting time. Hemorrhage after exclusion no longer acts to decrease the clotting time.

Nervous conditions play an important part in the coagulability of the blood. Stimulation of the afferent nerves, emotional excitement or pain, by their effect on the adrenals increase the coagulability of the blood. All these nervous conditions, especially pain, seem to act in the interest of the body in helping to reduce hemorrhage. Yet the use of anesthetics, such as ether and chloroform, hastens coagulation also by their effect on the adrenals. In the case of chloroform there is an additional action on the liver and the intestines in the release of thrombin elements into the blood. Antithrombin is inactivated by ether and chloroform, allowing free thrombin to clot fibrinogen in the presence of an oxidated plasma.

The theories and experiments in relation to the clotting time of the blood and the elements that tend to influence it have stimulated a desire to synthesize certain substances for the enhancement of the coagulability of the blood for use generally, but particularly in those cases having a disposition to uncontrollable bleeding after operation. Among the substances and drugs

recommended and devised are adrenalin, emetine, pituitrin, coagulin, thromboplastin, coagulose, normal horse serum, etc. Coagulin is an extract of blood platelets with the contained cytozyme. When combined with the serozyme of the animal blood it forms thrombin or fibrin element. Thromboplastin is prepared from the livers and brains of cattle which contain it. Coagulose is obtained by precipitating normal blood containing the necessary fibrin element. Normal horse serum has long been used to prevent and inhibit hemorrhage. In some individuals, however, there is an anaphylatic sensitiveness toward it. Most workers have obtained good results from one or other of these products and they should be used in every case where there are reasons to fear a low coagulability from constitutional or other causes, or where even a more rapid coagulability is required than the normal.

RADIUM AND CANCER.

THE value of radium in the treatment of cancer is probably increasing in the estimation of those who have had opportunities for testing it on a large scale and under the most favorable conditions. In order to derive the most satisfactory results from radium it is obvious that all the necessary details concerned in its application must be strictly adhered to. Of course, these details had first to be learned, and a good deal of the prejudice which has existed against the employment of radium has been due to faulty methods of application.

However, experience has taught to some extent the lesson, and in the future it is not so likely to be the technique which is at fault. With regard to the beneficial effects of radium therapy in cancer, information of a valuable character is given in a report written by Dr. Henry H. Janeway of the results of radium therapy at the Memorial Hospital, New York.* During the past two years 424 cases of malignant tumors have been treated with radium at the Memorial Hospital, so that the experience has been wide. It is interesting to note that it is only for a relatively short time that the hospital has had in its possession large quantities of radium, and therefore familiarity with the effects of large quantities, especially of large quantities heavily filtered, at varying distances from the surface of the skin, has been only recently acquired.

Janeway postulates the whole conception of radioactive therapy as based upon the belief that the tissues of malignant tumors are more susceptible to the influence of the radiations of radium than the normal tissues, and the aim of treatment is to take the greatest advantage of this difference by such a distribution of the source of radiation and by such a dosage that complete destruction of the malignant tissue is accomplished with a negligible damage to the normal tissues. In attempting to bring about this object close attention must be paid to the details of the procedure, and the fact must always be borne in mind that there is a considerable difference between the susceptibility of malignant and normal tissues to the action of radium, and the endeavor should be made to estimate as nearly as is possible how great this difference is. Janeway points out that the great susceptibility of rapidly dividing tumor cells indicates that the destructive effect of radium upon tumor tissue depends in part upon its direct action upon the nucleas of the cell. He is of the opinion that the cells of the majority of malignant growths, certainly tumors of the breast and rectum, are approximately four times more susceptible to the destructive action of the rays of radium than the normal tissue. It must be emphasized, however, that to obtain the best results, even in the case of superficial tumors, it is necessary, because of the rapid decrease of intensity of radiation with increasing distances from any applicator, to taks advantage of every technical procedure which will favor the uniform distribution of the radiation throughout the affected tissue. Uniform distribution of radiation is essential, for the reason that, owing to the selective action of radium on the cancer cells, it will be possible to furnish the cancer cells with a maximum fatal dose without at the same time producing an injury to the normal tissue. It is a matter of the utmost importance to avoid causing injury by radiation to the normal tissue, because such injury takes a long time to heal and is also accompanied by a proliferation of the connective tissue in the region exposed. Severe radium inflammations are objectionable, not merely on account of their chronic character but also because they materially diminish the probability of a cure. Consequently, as said before, it is of the first importance to insure a uniform distribution of the radiation. There is an optimum curative dose of radiations for cancer, and Janeway lays stress upon the fact that only small deviations from this optimum dose, particularly at the first treatment, will make all the difference between success and failure.

Janeway thus tabulates the methods best calculated to produce uniform distribution of radiation: (1) By numerous minute, unfiltered, or lightly filtered emanation tubes, 0.1 to 0.5 mm. German silver or 0.25 mm. aluminum. Such tubes are best supported in moulds made of dental composition, and their use is indicated in the case of all superficial lesions or the superficial portions of more advanced growths. (2) Central applications of one or more tubes, highly filtered, or relatively unfiltered except by the tumor tissue, and depending upon the limited character of the growth and the structure of the organ for the completeness of the radiation. (3) Deep radiation by the use of strongly filtered emanation tubes, arranged side by side, so as to form flat surfaces of emanation placed in direct contact with the tumor. (4) Distant, highly filtered emanation surfaces, placed either over the tumor so as

*Radium Therapy in Cancer at the Memorial Hospital, New York, by Dr. Henry H. Janeway, M.D. Published by Paul B. Hoeber, 1917.

to surround it from one side, or, better still, whenever possible, in a manner to surround the part of the body bearing the growth. The method is highly efficient, and provides fairly uniform radiation of all the deep tissues.

Up to the present time, radium has not been given the opportunity to demonstrate its value under the most favorable conditions. It has been perhaps too often employed as a last resort. In many instances it has had beneficial effects on advanced cancer, and, as Janeway says, such being the case, it is reasonable to believe that it will have the same complete action on early cancer without some of the disadtages, such as the effect on the nerves, the fibrosis, the dermatitis of the skin, which have not always been avoided with the use of large amounts of radium.

MILK INTOXICATION.

THE term "intoxication from milk" is used more or less vaguely. In connection with young nurslings we perhaps think first of local phenomena induced by some ingredient in the milk, and consisting of vomiting and diarrhea. The irritating substance, even if it causes violent symptoms, is not, however, technically a poison unless it enters the blood and attacks the viscera, especially the kidneys, during elimination. Marfan, in an article in *Le Nourisson*, abstracted in the *Journal de médecine et de chirurgie pratiques* for October 25, is opposed to the use of the term poison unless such can be shown to exist by definite tests. Nurslings vomit at times after the mother or nurse has eaten seafood or vegetables of the cabbage type, but no toxic substance can be recovered from the milk. Alcohol is hardly eliminated by the mammary gland, yet the nursling of an alcoholic mother may show marked nervous phenomena. When a mother takes a purgative her milk is diminished in quantity, although at times the child may seem to have absorbed some of the purgative. Certain substances, like arsenic, mercury, and colchicum, are known to find their way into the milk, and these, if any, should be able to poison the nursling. Marfan saw an apparent case of mercurialism in the nursling of a woman who was using intrauterine injections of sublimate, yet the presence of the drug does not appear to have been shown in the milk or in the nursling's urine. In menstruating nurses and recently vaccinated nurses the milk may disagree with the child, and this is true of feverish angina. Toxins may circulate in the blood in such cases and enter the milk, but of this we have no real evidence. Absorption must be minimal and effects transitory.

In artificial feeding the possibilities of actual poisoning are far greater. Chlorate of potassium has by mistake been added to milk for sugar, and hemolysis has followed, with intestinal hemorrhages. Milk preservatives belong in this category. Cows at times eat medicinal plants (colchicum), and various substances used as fodder, especially waste products from breweries and distilleries, lead to the production of a milk upon which the nursling, for whatever reason, cannot thrive. It is, however, only occasionally that these cattle foods seem unwholesome, and we are still in the dark as to the existence of definite toxic principles. When, as sometimes happens, the nursling shows an extraordinary intolerance to milk which is up to standard, we can only imagine an anaphylaxis, which involves the action of a toxic principle.

NON-SPECIFIC CHARACTER OF MERCURIAL STOMATITIS.

THE fact that mercury produces salivation and "touches" the gums causes us to take it for granted that the associated stomatitis is specific, although it is well known that the latter can be minimized by mouth hygiene. Favre, in an article abstracted in the *Journal de médecine et de chirurgie pratiques* for October 10, asserts that mercurial stomatitis is not a clinical entity, for the same symptoms can be produced by spirilla, and that the mere supervention of a stomatitis after ingestion of mercury is no proof of its specific character. In fact the mineral does no more than determine an irritable congestion of the mucosa. Buccal parasites do the rest and are equally in evidence in other kinds of sore mouth. The mercurial affinity for the mouth is of course due to its elimination by the salivary glands. It is possible to prevent the stomatitis by constitutional or local treatment, by administering arsenic with the mercury, and by the local use of silver nitrate solution, 1 to 100, applied after thoroughly cleansing the mouth by means largely mechanical. This treatment may be begun in the midst of severe stomatitis. The weak solution of silver is followed by one much stronger, say 1 to 15 or 1 to 20. This treatment is successful even when the patient continues his mercury.

THE PRESENCE OF SPIROCHÆTA ICTEROHÆMORRHAGICA IN BRAZILIAN RATS.

AN epidemic icterus is known to exist in parts of Brazil. Dr. MacDowell of Belém, in the State of Para, was responsible for the appearance of a graduation thesis upon this subject by Bentes. The attention of the Oswaldo Cruz Institute was called to this subject in connection with an assumed parasite, and Aragão began a study of the rats in Rio from this viewpoint while a Belém rat was sent to the institute by Bentes. Aragão makes a very brief preliminary report on his finds in the *Brazil-Medico* for September 29. The kidneys of the suspected rats were minced and the resulting mash was diluted with saline infusion and injected into the peritoneal cavity of guinea pigs. Within 10 days animals injected with this material died with total icterus and hemorrhagic foci in the lungs and stomach. Emulsions of guinea pigs' liver conveyed the disease in like manner to others. A spirochete was now found in all the organs of the second inoculated group, and in special numbers in the liver, which agreed in all its characteristics with the *Spirochæta icterohæmorrhagica*. The author awards high praise to the clinical intuition of MacDowell in making a diagnosis of the disease where its presence was not even suspected.

News of the Week.

Smallpox in Pennsylvania.—Dr. Samuel G. Dixon, State Health Commissioner, has issued a statement telling how during the last few weeks 38 cases of smallpox have appeared in widely separated portions of the State, all of which could be traced to three carriers of the disease. There is an epidemic of smallpox in Clearfield County, Pa., which is directly due to the fact that a case of smallpox was secreted and the knowledge of it was kept from the health authorities.

State Troopers Maintain Quarantine Against Smallpox.—An outbreak of smallpox in the Cattaraugus Indian Reservation in New York State recently made necessary the quarantining of the entire reservation. As the reservation is seven and one-half miles in length by three in width, it was found that it would cost $100 a day to guard this territory satisfactorily. In order to avoid this expenditure the State Department of Health requested that a body of State Troopers be detailed to guard the reservation. The reservation was effectively surrounded by mounted troopers, and quarantine satisfactorily maintained.

American Child Needs Physical Training.—Dr. Isaac W. Brewer, M. R. C., U. S. A., in the November *Bulletin* of the New York State Department of Health points out that the physical examinations made at the recruiting stations of the army show the need of rational physical training for American children. He states that of 278,537 applicants for enlistment during the period from 1914 to 1917 205,281, or 73.7 per cent., were rejected at the recruiting office because of physical defects that were apparent to a man who had no medical training. At the recruiting stations, where the men were subjected to a rigid physical examination by a medical officer, an additional 3.6 per cent. were rejected, making a total of 77.3 per cent. rejected. Of 4,027 men from New York State examined at the recruiting depots, 17.6 per cent. were rejected. During April, May, and June, 1917, 1,833 applicants from New England and part of New York State were examined by several medical officers, and 7.6 per cent. were rejected. Not less than 56 per cent. of the men were rejected because of diseases or deformities that were preventable or could have been removed by surgical operation.

Mortality Statistics for 1916.—The Bureau of Census, Department of Commerce, Washington, D. C., has just made a preliminary announcement with reference to the mortality statistics of 1916. These statistics cover the registration area of the United States, which contains about 70 per cent. of the population. During the year there were 1,001,921 deaths, nearly one-third of which were due to the three causes—heart disease, tuberculosis, and pneumonia—and nearly another third were charged to the following nine causes: Bright's disease and nephritis, cancer, apoplexy, diarrhea and enteritis, influenza, arterial diseases, diabetes, diphtheria, and typhoid fever. The number of deaths per 100,000 population of the more common diseases were as follows: Heart disease (organic diseases of the heart and endocarditis), 159.4, as against 123.1 for 1900; tuberculosis, 141.6, as against 200.7 in 1904; pneumonia, 137.3, as against 180.5 in 1900; Bright's disease and acute nephritis, 105.2, as against 89 per 100,000 in 1900; cancer and other malignant tumors, 81.8, as against 63 in 1900; apoplexy, 81.3, a gradually increasing rate; diarrhea and enteritis, 79.3, as against 133.2 in 1900; influenza, 26.4, which is higher than any year since and including 1900, with the exception of 1901, when it stood at 32.2; arterial diseases, 23.9, as against 6.1 in 1900; diabetes, 17, as against 9.7 in 1900; diphtheria and croup, 14.5, as against 43.3 in 1900, a decline of 67 per cent., which is greater than that shown by any other important cause of death; typhoid fever, 13.3 in 1916, as against 35.9 in 1900. Measles, whooping cough, and scarlet fever together caused 24.6 deaths per 100,000 population in 1916. In 1913, measles caused more deaths than either of the other two diseases, and in 1914 and 1915 whooping cough had first place. The rate for scarlet fever for 1916 was the lowest on record, 3.3. Acute poliomyelitis caused 10 deaths per 100,000 population. The rate from this disease declined from 2.7 per 100,000 in 1910 to 1 per 100,000 in 1915. The rate for 1916 was ten times as great as for the preceding year. Deaths resulting from accidents in 1916 numbered 60,071, corresponding to a rate of 83.9 per 100,000. This rate is considerably in excess of that of 1915, which was 76.3. The most marked increase was in deaths due to railroad and automobile accidents and for those resulting from the effects of heat. The death rates from these causes have advanced continuously since 1906. There were 2.3 deaths per 100,000 population caused by machinery accidents and 3 per 100,000 caused by mine accidents. Deaths from these causes have shown a material decline since 1910. The death rate from heat was 2.9 per 100,000, the highest rate shown from this cause in the last fifteen years. The suicide rate was 14.2 for 1916, the lowest for the past ten years. The suicidal use of firearms shows a decline as compared with 1914 and 1915, but an increase as compared with the period just previous to those years. Despite the decline in the number of deaths from tuberculosis, this disease causes more deaths annually than any other malady except heart disease, and about 37 per cent. more than all external causes, accidents, homicides, suicides combined.

Two Committees at Work for New Drug Laws.—The Whitney Legislative Committee met on November 28 and decided to make a thorough investigation of the drug evil as it exists in this city. A series of hearings has been arranged for at which testimony will be taken regarding the various phases of the drug traffic. A special effort will be made to have drug victims themselves appear before the committee and tell how they get their supplies. The aim of the Whitney committee, according to Senator Whitney, is to put the law in such shape as to prevent future addiction and to cure as many of the present addicts as possible. At the same time that the above committee was in session the New York City Committee on Drug Evils met in the Criminal Court Building. The members of this committee agreed that what was most needed was Federal control of a definite and comprehensive sort. It was shown that the present laws had checked the sale of drugs in the underworld, but that an illegitimate traffic had developed among un-

scrupulous physicians, and had even penetrated some of the army camps. A bill was submitted for consideration which provides that the Government shall restrict the sale and manufacture of narcotics through the imposition of a tax which would tend to make the distribution of drugs for any but legitimate purposes prohibitive. This bill will be submitted to Government officials at Washington.

New York City Example in Food Saving.—The Food Administration has issued a statement showing the immense saving of meat and wheat through the observance of meatless and wheatless days and other conservative measures adopted by the hotels and restaurants of the city. The figures show that the hotels and restaurants of the city are doing more than the homes of the nation to save food for the European nations. The actual figures show that on November 13 the saving in meats amounted to 193,545 pounds, or 96.75 tons. The saving of wheat flour on November 14 was 101,295 pounds, or 517 barrels. By the use of whole or partial substitutes for wheat flour, the saving in wheat flour for the week of November 12 was increased to 121,554 pounds, or 620 barrels. If the hotels and restaurants of the whole country were saving as are those of New York, John McE. Bowman, chief of the hotels division of the Food Administration, believes this industry alone will save sufficient to furnish several shiploads of meats and wheat each week to send to our armies and allies.

Licenses to Make Salvarsan.—The Federal Trade Commission has licensed three firms to manufacture and sell salvarsan, patent rights of which have been held by German subjects. The orders for licenses are subject to acceptance and agreement by the licensees to the stipulations made by the commission. Hereafter this drug will be manufactured and sold under the name of "Arsphenamine." The Public Health Service has prepared rules and standards and will supervise its manufacture. The *Official Bulletin* announces that the three firms which will be permitted to manufacture and sell arsphenamine are: Dermatological Research Laboratories of Philadelphia, Takamine Laboratory, Inc., of New York, and Farbwerke Hoechst Co. (Herman A. Metz Laboratory) of New York. The original patent was issued to Paul Ehrlich and Alfred Bertheim, German subjects, and assigned to Farbwerke Vormals Meister, Lucius and Bruning, of Hoechst on the Main, Germany. Before the war began the patented drug was sold at $4 per dose, which is approximately $3,500 per pound. While the price of the product is not fixed at this time by the commission, the right to fix prices is retained, and $1 per dose to the Army and Navy, $1.25 per dose for hospitals, and $1.50 per dose for physicians, are the prices at which some, at least, of the licensees have stated that they intend to offer the drug.

Medical Colleges Form Merger.—Bennett Medical College and the Chicago College of Medicine and Surgery have united to form the medical department of Loyola University of Chicago. The purchase of the buildings and equipment of the Chicago College was recently made by Loyola University officials. Dr. Lawrence Ryan has been appointed dean of the new faculty of the school; Dr. Alfred de Roulet is junior dean, and Dr. G. E. Wyneken is secretary.

Hospital Destroyed by Fire.—The Hotel Dieu Hospital at St. Hyacinthe, Quebec, was destroyed by fire on November 28. All of the inmates, about 1000 in number, were removed to safety. The institution consisted of three stone buildings erected at a cost of $600,000.

National Board of Medical Examiners.—The next examination of the National Board of Medical Examiners will be held at Bellevue Hospital, New York, January 9 to 17, 1918. The board points out that its certificate confers many advantages; the holder is given a commission in either the medical corps of the Army or Navy without further medical examination. Twelve States now recognize the certificate of the board for licensure, and as many more will do so as soon as their examining boards have received authority from the legislatures. Medical officers in training camps near New York who contemplate taking the examination should apply for information and also for leave of absence to cover the dates of the examination. Further information may be obtained by writing to the secretary, Dr. J. S. Rodman, 310 Real Estate Trust Building, corner Broad and Chestnut Streets, Philadelphia.

Harvey Society Lecture.—The fourth of the present series of lectures will be delivered at the New York Academy of Medicine on the evening of December 8, at 8.30 o'clock, by Prof. A. S. Warthin of the University of Michigan. His subject is "The New Pathology of Syphilis."

The Medical Society of the County of New York at its one hundred and twelfth annual meeting, held on November 25, elected the following officers: *President*, Dr. Howard C. Taylor; *First Vice-President*, Dr. Charles H. Peck; *Second Vice-President*, Dr. Samuel A. Brown; *Secretary*, Dr. Daniel S. Dougherty; *Assistant Secretary*, Dr. J. Milton Mabbott; *Treasurer*, Dr. James Pederson.

Dr. William Seaman Bainbridge of New York has had the degree of LL.D. conferred upon him by the trustees of Lincoln Memorial University.

Court Action in Alleged Medical Negligence.—The charge of manslaughter against Dr. Paul A. Barrett of Forest Hills, L. I., has been dismissed by the courts. In this case it was charged that the physician had been negligent in the treatment of a two-year-old child in that he had given an overdose of codein. The County Court of the Borough of Queens dismissed the case, stating that as there had been no autopsy before the body was cremated no other course was open to the court.

Cost of Health Supervision in Industry.—A recent publication issued by the Conference Board of Physicians on Industrial Practice shows the cost of health supervision in industry. The compilation is based on data for 1916 as reported by 99 industrial plants of many varieties located in fifteen States. The total average number of employees was nearly 500,000. It is shown that the average annual cost of medical and surgical supervision per employee was $2.21.

The Southern Medical Association, which held its eleventh annual meeting at Memphis, Tenn., on November 15 and 16, elected the following officers: *President*, Dr. Lewellys F. Barker of Baltimore, Md.; *First Vice-President*, Dr. William H. Deadrick of Hot Springs; *Second Vice-President*, Dr. T. C.

Halloway of Hazard, Ky.; *Secretary-Treasurer*, Dr. Seale Harris of Birmingham, Ala., having been granted leave of absence during his term of service in the Army, Dr. M. G. Dabney of Birmingham, Ala., was appointed acting secretary and editor of the *Southern Medical Journal*.

The Fourth District Medical Society of Texas, which met in Brownwood, Tex., on November 6 and 7, elected the following officers: *President*, Dr. J. E. Dilley of Brownwood; *Secretary-Treasurer*, Dr. J. W. Blasdell of Ballinger.

The Chattanooga County Medical Society, organized on November 11 and elected the following officers: *President*, Dr. B. F. Shamblin of Lyerly; *Vice-President*, Dr. W. D. Medlin of Summerville; *Secretary and Treasurer*, Dr. H. D. Brown of Lyerly.

Obituary Notes.—Dr. ALOYSIUS KESSELER, retired, a graduate of New York University Medical College in 1876, died at his home in New York City on November 30, at the age of 74 years.

Dr. THOMAS F. MOSES, a graduate of Jefferson Medical College, Philadelphia, in 1861, died at his home in Waltham, Mass., on November 21, aged 81 years.

Dr. FRANK MORTIMER WINCHESTER, a graduate of Jefferson Medical College, Philadelphia, Pa., in 1880, died at his home in Charlotte, N. C., November 11, at the age of 60 years.

Dr. HENRY RODEMICH of St. Louis, Mo., a graduate of the Marion Sims College, St. Louis, Mo., died of apoplexy, on November 10, aged 53 years.

Dr. M. L. WITHER, a retired physician of Bristol, Tenn., died in a hospital near Richmond, Va., on November 12, aged 76 years.

Dr. ABRAM PHILIP FETHEROLD died at his home in Allentown, Pa., on November 20, aged 74 years. He was a graduate of Bellevue Hospital Medical College, in 1865.

Dr. WILLIAM E. HENKEL, a graduate of the Louisville School of Medicine, in 1885, died at his home in Hammond, La., on November 8, aged 56 years.

Dr. PAUL H. MORRISON of Rushville, Mo., a graduate of the Central Medical College of St. Joseph, Mo., died in a hospital in Atchison, Kan., on November 2, aged 37 years.

Dr. THOMAS LUBBOCK KENNEDY died at his home in Galveston, Tex., after a brief illness, on November 9, aged 47 years. He was a graduate of the University of Texas Medical Department, in 1895, and was chief surgeon of the Galveston, Houston and Henderson Railway Company.

Dr. ALONZO G. TRAFTON, a graduate of the Medical School of Maine, in 1877, died after a brief illness at his home in South Boston, on October 29.

Dr. SIGMUND DEUTSCH died at his home in New York City on November 30, aged 41 years. He was a graduate of the College of Physicians and Surgeons of Columbia University in 1902, attending physician to the German Hospital Dispensary and Vanderbilt Clinic, and a member of the Army Medical Reserve Corps, expecting to be called to the service in the near future.

Dr. NATHANIEL BABCOCK DARLING, a graduate of the College of Physicians and Surgeons, Columbia University, in 1873, for forty-four years a practitioner of medicine, died at his home in Brooklyn, N. Y., November 29, aged 83 years.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

NEW UNIVERSITY HEADQUARTERS—EXPANSION OF THE AMERICAN RED CROSS.

PARIS, October 30, 1917.

THE American University Union in Europe has secured as its Paris headquarters the Royal Palace Hotel, 8 Rue de Richelieu and Place du Théatre-Français. Its exclusive occupancy of the hotel began October 20. The central location and excellent accommodations of the University Union will make it an attractive center for all American college men and their friends in Paris. It will afford the customary advantages of an American university club, including bedrooms and numerous bathrooms, an excellent restaurant where meals will be served separately or "en pension," and lounging and reading rooms plentifully supplied with American newspapers, magazines, and the college registration, which will be of special service to men desiring information as to Americans in military or war relief service in France. A unique feature of the Union will be the special bureaux within it already established by a number of American universities, including Harvard, the Massachusetts Institute of Technology, Michigan, Princeton, and Yale, in charge of official representatives. The interests of other colleges will be similarly served by the general staff of the Union.

Some thirty universities and colleges have already joined the American University Union, thus entitling all their members, without individual initiation fees or dues, to its privileges. The Paris headquarters, however, will be open to all American college men, whether graduates or not, and to guests regularly introduced by them. Men from colleges not belonging to the Union and all introduced guests will be given the advantage of the fixed tariff accorded to its members, but will be charged a nominal Union fee in addition if they have rooms at the Union. Thus, in every way, the American University Union will, to the extent of its capacity, serve the general interests of a very considerable number of Americans now in service abroad.

The American Red Cross has come to France under circumstances which have no parallel in history. The war which has gone on for three years has drawn into it the entire life of the belligerent nations. Every resource, every unit of strength, every person in France, is, as a matter of fact, engaged in the war, and all of them are suffering from the war. The American Red Cross, therefore, not only aims to help the sick and wounded soldiers, but it has established a Department of Civil Affairs, as in the United States.

This Department of Civil Affairs has asked the question: What are the present actual immediate needs, in view of the three years of war? The Red Cross is by no means entering a virgin field, for France has done wonders through governmental agencies and through private committees. What are the remaining immediate needs? Wherever and whenever that question is asked one hears of

the problem of refugees, "rapatriés," devastated regions, "mutilés," tuberculosis, and children.

The "rapatriés" are arriving at Evian 500 to 1,000 per day, after three years of hardships under alien rule. There exists the splendid organization worked out by the French government and the Citizens' Committee of Lyons for their reception, but inevitably, here also, no agencies could wholly meet such an unprecedented task. The need first impressed upon the attention is that of more ambulances and automobiles to help to get the sick and aged from the railway station to the central clearing house and to the hotels and hospitals in which they find a temporary resting place. The American Red Cross sent eight automobiles and ambulances, with a full corps of drivers, who have been working daily from 7 in the morning until midnight with a good will. Three or four more are to be sent. Inevitably in war time physicians for civilians are scarce throughout France. The American Red Cross, therefore, aims at aiding in the medical care of children at Evian. It has leased one of the large hotels at Evian, which it hopes to open in a very short time as a reception hospital for sick "rapatrié" children. It also intends to establish a children's hospital near Lyons for such children needing longer care.

In the devastated regions there are immediate needs, and there are future needs. The immediate needs are shelter, clothing, furniture, and, in some cases, food. To help in some slight degree toward meeting these immediate needs they have certain district delegates, who keep in touch with the local authorities and organizations, no matter whether they are French, English, or American. In a small way they are beginning the provisional repair of structures, in which certain of the refugees that have returned can find shelter until such time as more permanent reconstruction can be provided for.

Besides these emergency war needs there are two others which are, perhaps, more significant for the future welfare of the French people. In all countries tuberculosis is one of the greatest enemies to human welfare. The Department of Civil Affairs of the American Red Cross, working with the tuberculosis commission of the Rockefeller Foundation and in the closest cooperation with public authorities and private organizations dealing with tuberculosis, are converting a chateau at Ypres into a sanatorium, this particular enterprise having been taken over together with the funds from the Edith Wharton committee. They are providing additional equipment, food, and facilities for the comfort and recreation of those in the tuberculosis hospitals erected on the grounds of general hospitals in the city of Paris. They are hoping to do work of the same kind for the patients in the tuberculosis hospitals outside Paris.

Lastly, and perhaps most important of all, they have been permitted to take some little part in the great work of conserving the childhood of France. M. Mirman, prefect of the Department of Meurthe-et-Moselle, has given them the opportunity to help in the operations of his children's asylum at Toul for young children driven from the regions in the rear of the lines by gas attacks. One of their physicians, a specialist in children's diseases, will start in a day or two for Nesle with a unique equipment for taking medical care to the children of that devastated region. They are arranging to establish child welfare dispensaries in connection with the tuberculosis dispensaries wherever those may be organized, and they hope to strengthen the already admirable work carried on in France for the reduction of infant mortality.

I would, however, emphasize the fact that the American Red Cross is a late comer in these fields, that the most it can do will be only a very small contribution when compared with the tremendous work which has been done and will continue to be done by public authorities and private organizations.

Progress of Medical Science.

Boston Medical and Surgical Journal.

November 22, 1917.

1. Wounds of the Knee-Joint. Berkeley Moynihan.
2. The Founding of the Berkshire District Medical Society, with Notes on the First Period of the Existence of the Massachusetts Medical Society. Walter L. Burrage.
3. Progress in Gynecology. Stephen Rushmore.

1. Wounds of the Knee-Joint.—Berkeley Moynihan states that there is probably no department of surgery in which greater changes have been wrought since the early days of the war than in that concerned with the treatment of wounds of the knee-joint. When he was first in France in November, 1914, the majority of the cases of wounds of this joint exhibited, by the time that a base hospital was reached, a grave suppurative arthritis; very often the patient was extremely ill, with a high temperature and all the evidences of a severe constitutional infection; and in a large number of cases only the most drastic procedures offered any hope that the limb might at last be saved. Too often, perhaps, they failed to remember that a man had two legs, and only one life, and conservative measures were pushed to excess. In the work of the French army, as he saw it, amputation was in such circumstances often advocated and practised forthwith; and there can be no doubt, that though some limbs were sacrificed which continued care might have saved, many lives were rescued that would otherwise have been jeopardized or lost. Gradually as surgical knowledge increased, and transport facilities improved, cases were obtained earlier and a more direct attack was made upon the wounds with improvement in results. He classifies the injuries as follows: Cases of clean perforating wound of the knee-joint by rifle bullet. Cases of penetrating or perforating wounds of the joint with a larger aperture of entry, or of exit, or of both, when the projectile is retained in the joint. Cases of perforating or penetrating wounds of the joint with intra-articular fracture. Cases of injury to the knee-joint, with extensive fracture of the articular ends. He offers the following conclusions in the handling of these cases: (1) In all cases of wounds of the knee-joint, the limb should be fixed immovably upon a splint at the earliest possible moment, and until circumstances and surroundings permit of a complete operation. (2) At the casualty clearing station, or other operating center, an *x*-ray examination is made in all cases. The whole limb is then prepared for operation. (3) The following are the essential features in all operations: excision of the wounds and of the track of the projectile after preliminary sterilization by the cautery or otherwise; a free exposure of the joint either by enlarging existing incisions or by long internal or external incisions or by the formation of a flap by division of the patellar ligament. (4) All foreign bodies must be removed from the joint. Even the smallest piece of clothing or of metal may be the nidus of a continuing infection. (5) The wounds are closed in layers by catgut sutures. Drainage is secured by leaving a gap in the line of suture of the synovial membrane, or by leaving a tube close "down to but not into" the joint. (6) Drainage

tubes are never placed within the joint cavity. They do not drain the joint, they are harmful in their effects upon the delicate synovial membrane, and they are often a channel by means of which infection is conducted to the joint. (7) In cases of severe infection of the joint by staphylococcus, or especially by the streptococcus, the wounds must be reopened, the synovial membrane stitched to the skin, free drainage of the joint secured, and the Carrel-Dakin or other method of progressive sterilization of the wound adopted. In more severe cases, with an infection rapidly gaining ground, excision of the joint may be necessary. (8) In cases of severe comminution of the articular ends with much loss of substance (the whole of one condyle, for example), a resection of the joint is performed forthwith. (9) In severe and extensive wounds with heavy infection, the method of resection with wide, temporary separation of the ends of the bones (Fullerton) should be practised. (10) In cases of very extensive damage, especially with infection, amputation is desirable.

3. Prophylaxis in Syphilis of the Central Nervous System.—Isadore Rosen states that the importance of the early recognition of syphilis of the nervous system is best appreciated when one visits a large institution for the treatment of the disease and its complications, and is brought face to face with an endless chain of hopeless and incurable cases of conditions which we now feel could have been prevented if our present diagnostic methods had been in vogue twenty years ago. Not until the medical profession in general recognizes the necessity of early lumbar puncture as a routine measure in all cases of syphilis shall we be able to prevent optic atrophy, tabes, and paresis, for it is only by anticipating the ravages of the spirochete during the early latent period that we can hope to eradicate the disease and prevent secondary degeneration. Since it has been proved by Fordyce and others that involvement of the nervous system takes place in the secondary period of the infection, why wait until we are ready to discharge the patient as cured, as shown by repeated negative blood tests, before ascertaining the status of the spinal fluid? At the Vanderbilt Clinic it is their aim to puncture all secondary cases early, that is, after about the third month of their infection. In primary cases with a negative Wassermann there is less liability of involvement unless a later generalization of the organism should take place, as shown by a positive Wassermann, and puncture is not here insisted upon until after a regular course or courses of treatment. Up to a year ago they were content to defer lumbar puncture, unless clinical symptoms of neurosyphilis were present, until just before the dismissal of the patient as cured. They have come to the conclusion, however, from the study of a large number of cases that this involves unnecessary delay and that it is to the patient's interest to determine the findings in his fluid, whether he is without signs or is just beginning to show some pupillary abnormality or other neurological symptom, in order that they may prevent an advancing pathological condition by prompt and intensive treatment. What is our present conception of prophylaxis in syphilis of the central nervous system? Does it imply that infection of the cerebrospinal axis is preventable? This must be answered in the negative except for cases of primary syphilis where early energetic treatment kills the spirochetes *in loco*. When the disease has become constitutional investigation has shown that the spinal fluid of the individual who is to become the victim of neurosyphilis is already infected. He summarizes the necessary efforts towards prophylaxis of this condition as follows: (1)Since infection of the central nervous system takes place during the early secondary period, the spirochetes remaining dormant for months or years without producing signs or symptoms of a morbid process, it is imperative that a routine lumbar puncture should be carried out early in the secondary stage of all syphilitics if neurological complications are to be prevented. Spinal puncture properly performed is a harmless procedure and while the headache which follows in so many cases may incapacitate the patient for several days, the discomfort is well worth the information which can only be gleaned from cytobiological examination. (2) Early and repeated examination of the eyes and nervous system should be made in the case of every patient in order to detect any changes in their inception. (3) Careful serological observations should be employed as a guide for the indication or contraindication of intraspinal medication. (4) Systematic and intensive treatment, both intravenous and intraspinal, should be administered to patients with a strongly positive spinal fluid. (5) If tabes, paresis, optic atrophy, and other grave conditions are to be prevented interference must occur early, and by so doing the new school of syphilology which with its modern serological and therapeutic measures stands for progress and prophylaxis will soon be looked upon as a great blessing to mankind, notwithstanding the adverse criticism of some of our colleagues. (6) Every clinic for the treatment of syphilis should have facilities for all the special examinations necessary and an infirmary where the proper therapy can be employed. It should be emphatically insisted upon that no clinic be allowed to treat the disease unless it can comply with the qualifications specified. In this way only can the secondary complications from syphilis be eradicated or reduced to a minimum.

8. Ten Years' Experience With the Grading of Milk.—Henry Field Smyth, Acting Secretary, Board of Health, Radnor Township, Delaware County, Pa., tells of what has been accomplished since 1907 in this township with reference to the betterment of milk. Radnor Township, being a rural community of the better class, the dairy farms are owned and run in many instances by gentlemen farmers with whom dairying is a hobby, as well as a large number of dairy farms owned and managed by the regular farmers. Strict impartiality was shown in enforcement of the necessary rules, and it occasionally happened that, on account of carelessness in the dairy, one of these farms of the richer set would be summarily removed from the grade of excellent or good class to the fair or even poor class. Smyth states that on two occasions, not the same one each time, one of these dairies has been forbidden to sell milk at all until conditions were improved. The aim

of the board has not been so much to do police work and punish delinquents as to do missionary work and encourage the dairymen to be constantly improving conditions. It has seldom been necessary to prosecute delinquents, and after the first natural opposition to a new plan, the dairymen have come more and more to welcome the visits of the milk hygiene agent and to look to him for advice and help in planning improvements. In 1916 the agent received forty-seven requests for such help; the majority of these were during the poliomyelitis epidemic. Also, advice has been solicited in the selection of a dairy. The board has divided the grading of the milk into practically six classes according to the bacterial colony count. Class A cannot have over 10,000 per c.c., with no disease-producing germs or peptonizers, while the cattle furnishing this milk have undergone the tuberculin test in a dairy scoring not less than 90 out of 100 points on the score card, which entitles to the rating of an "excellent dairy." Class B allows of a bacterial colony count not over 100,000 per c.c., including practically the same A conditions and a dairy scoring of 80 per cent. on the score card, which gives a rating of a "good dairy." Class C allows of not over 500,000 per c.c. in the bacterial count, with a dairy scoring card of 70, and rated as a "fair dairy." Class D is pasteurized milk having a bacterial count of not over 1,000,000 per c.c. before pasteurization and not over 50,000 per c.c. after pasteurization with no disease-producing organisms. Class E includes all raw milk with a bacterial colony count of over 500,000 per c.c. from dairies with a score card under 70. Certified milk from farms having the certificate of the Philadelphia Pediatric Society forms the sixth class, and is practically of the same grade as Class A milk. Smyth states that in the beginning there were over 59 per cent. of poor dairies, over 20 per cent. of fair, over 18 per cent. of good, and less than 3 per cent. of excellent dairies. A gradual improvement has been found in dairy conditions with very little change having taken place in the certified or pasteurized classes, but with a big improvement in Classes A, B, C, and E. There was a decided decrease in the number of producers in E, due to the fact that in April, 1916, the board prohibited the sale of Class E milk unless it was labeled as "cooking milk." This resulted in all of the Class E producers who would not or could not improve conditions going out of business. Of the eighteen producers in this class in 1915, one-half, when they found it necessary, succeeded in moving up into Class B or C, while the other nine simply stopped producing milk for sale. There has been a decrease in the total number of dairies in 1917. This was due not only to strict enforcement of rules, but to economic conditions. Smyth considers, however, that this condition is probably less marked in this township than in many other places, since, owing to the careful supervision of the milk supply, the consumers are more ready to pay a fair price for milk. When this work was begun milk sold for from 5 to 8 cents a quart, while now few producers get less than 12 cents.

8. A Case of Epilepsy Cured by Removal of Calcareous Intracranial Tumors. Theodore Thompson and Albert J. Walton.

2. Observations on Circulatory Inefficiency.—E. B. Gunson based his investigations mainly upon a clinical study of the nervous and circulatory phenomena occurring in diphtheria and dysentery, in which two distinct types of circulatory inefficiency were encountered in diphtheria. One is always preceded by the onset of arrhythmia and has long been attributed to a state of "cardiac paralysis." In the second form a normal rhythm is maintained even in fatal cases. Cases which maintain a normal rhythm he classes as under the vascular type; while cases which develop a marked arrhythmia with rapid pulse and in which paroxysms of regular tachycardia may occur he places under the cardiac type. The first type—normal rhythm—are usually fatal within the first ten days of the disease, and present the appearance of profound exhaustion. The pulse remains regular, but soon becomes weak and frequently disappears entirely from the wrist. The heart, however, continues to act until within a few hours of death. Consciousness is retained throughout, apathy is marked, and death is usually preceded by a convulsion. The sequence of events points to a primary failure of the peripheral circulation leading to venous stasis and engorgement with subsequent embarrassment of the heart. The terminal convulsion is attributed to cerebral congestion. Involvement of the capillaries is shown by purpuric eruptions and gastric submucous hemorrhages and subcutaneous hemorrhages. In the second class, "cardiac paralysis," a syndrome including marked cardiac arrhythmia, increase in cardiac and liver dulness, and triple rhythm on auscultation is present. The pulse remains of comparatively good strength till the arrhthymia has persisted for several hours at least. The onset of the arrhthymia, due usually to the presence of frequent premature contractions, and often associated with paroxysms of regular tachycardia, occurs usually in the third week, but may be preceded by premonitory signs of the same for several days. Such cases rally frequently and may make a complete recovery. Congestion of the lungs is absent except as an occasional terminal event. In fatal cases marked signs of circulatory failure are frequently wanting at the time of death, which is due to failure of respiration, to which a diaphragmatic palsy or bronchopneumonia may be contributory. Among the nervous symptoms presented in these cases there is a crossed leg reflex which is held to indicate a definite spinal cord lesion, a point of special importance.

1. An Address on Injuries to the Peripheral Nerves and Their Treatment.—Berkeley Moynihan gives four divisions of lesions of the nerve trunks as the result of wounds. He considers that in the majority of cases the nerve trunk has not sustained a primary injury, but it may be exposed more or less in a wound of the soft parts with or without fracture. The nerve fibers may or may not have been directly, or only trivially implicated, but the projectile may have passed so near the nerve trunk as to have opened its sheath. The nerve then becomes adherent to the track of the missile, and a mass of fibrous tissue is found firmly welded to its lateral aspect. The nerve may have been partly severed by a projectile, or a fragment of bone. In the second instance a central neuroma may occur, while in the latter case a lateral neuroma might result. Again the nerve may be completely severed, causing a gap between the divided ends; while bridging this interval there may be a connecting band of fibrous tissue, or a blurred mass of scar material in which both cut ends are lost. In this case a terminal neuroma may be formed. Experience has shown that the musculospiral nerve was injured in 25 per cent. of the cases; the ulnar in 24 per cent.; median in 14 per cent.; sciatic and external popliteal in 12 per cent.; internal

popliteal and anterior crural in 1 per cent.; lower portion of the brachial plexus in 7 per cent., and the upper portion of the same in 4 per cent. A positive reaction to faradism is regarded as a contraindication to operation, but failure to respond gives no definite information, for voluntary movement may return after nerve injury before the faradic response. The muscles are next investigated by a constant current. The character of the contraction is important. A brisk twitch may indicate the presence of some conducting nerve fibers in the tested muscle, while a slow "vermicular" response is usually associated with a complete interruption of nerve fibres. A condenser is next used on the nerve muscle. The method depends upon the fact that a condenser discharge through a constant resistance gives a current which varies in duration according to the capacity of the condenser used. The more severe the damage to the nerve the greater will be the capacity of the condenser required to excite it; or, in other words, the longer the duration of the current the more chance there is of obtaining a response in such a nerve muscle. Thus a definite measurement of current of condenser used may be noted, and future progress may be accurately followed. Complete absence of both faradic and galvanic response is an indication for early operation, and the cases which require careful and repeated examinations are those where there is pressure on the nerve trunk by a contracting scar. In total loss in some fibers the nerve is tested both above and below the site of injury, in which case special sterilizable electrodes with long connecting cords which can be boiled are used. The nerve is gently lifted upon two small glass hooks and a very weak faradic current used. Operation is decided upon in cases of complete division, in cases of the same where progress is arrested, and where there is severe neuralgic pain, "causalgia." Operation is deferred for one month after the closure of the wound where soft parts only are injured, also for two or three months after complete closure of the wound where there is an involvement of bone, and definitely deferred so long as progressive signs of recovery in nerve functions continue. The suture of the nerve may have to be delayed until unsatisfactory joint conditions are improved. Contractures of the knee, for example, should be corrected before the sciatic nerve is sutured, otherwise the nerve would be in danger of rupture if the deformity were subsequently rectified. In other cases the nerve may be sutured and the joint dealt with at the same period and subsequently. Moynihan considers it to be of first importance to start active measures to prevent or remove stiffness and deformity in the parts supplied by a wounded nerve, which can be done for many weeks before it is possible to repair the nerve. He further states that it is not sufficiently realized that a nerve to be of use after suture must act upon live and supple tissue, therefore joints and muscles must be kept in condition for the nerve impulse which some day will come to them again. In operating Moynihan discourages the use of a tourniquet for two reasons: It is possible to harm the nerve, or other nerves in the limb if the rubber band is applied too tightly, and for the long period sometimes necessary in this procedure; and when the operation is complete and the tourniquet removed, there will probably be an escape of blood into the wound—a thing in these cases most undesirable. In these wounds there is often a good deal of young fibrous tissue, from which free oozing may occur in the period of hyperemia which follows removal of a tourniquet. He also does not approve of the fashion employed by some surgeons of surrounding the sutured nerve with some material supposed to have protective power, either a piece of vein or fat wrapped round the nerve for the purpose of insulating it in its new position. He considers that this method is often harmful and is doubtful if it ever helps. In the diagnosis and treatment of an organic lesion of a nerve it should never be forgotten that there may be added a functional disability. It is always desirable to remove this difficulty in order to appreciate the organic condition. This is particularly important when the organic lesion is well on the way to recovery. Thus in a recovering lesion of the inner cord of the brachial plexus it may be impossible for the fingers to be flexed until re-education has trained the laggard muscles into obeying orders from headquarters. He summarizes the results of his experience as follows: (1) The earliest examination should be made of all wounds in which division of a nerve trunk is probable. If at the casualty clearing station such a lesion is found, end-to-end suture should be adopted forthwith. This is more likely to be possible in cases where primary suture of the wound, after excision, is found practicable. (2) If secondary sutures of the wounds, after the Carrel-Dakin method has been practised, is to be undertaken, the union of divided nerves should be secured at the same time. (3) If these methods have been attempted and have failed, they do not prejudice the later union of the nerve. On the contrary, they probably ensure that an easier and more satisfactory operation can then be practised. (4) Throughout the whole period before late nerve suture is attempted the strictest attention must be paid to the relaxation and nutrition of all paralyzed muscles, to the maintenance of suppleness in all joints moved by these muscles, and to the preservation of the integrity of the skin. (5) Operations upon nerve trunks demand the most scrupulous observance of the ritual of asepsis. There must be the greatest gentleness of manipulation; the nerve must not be injured by instruments or by the surgeon's finger; it must not be separated from its sheath or disturbed overmuch from its bed; it must not be chilled or allowed to dry. All sutures must be of fine catgut, and introduced with most punctilious accuracy. Axial rotation of the nerve must be avoided. The cut ends of the nerve before approximation must show clearly the fibers of which the trunk consists. (6) Nerve-grafting is of little or no value; nerve anastomosis is to be sharply condemned; the turning down of flaps from the nerve to bridge a wide gap is useless. (7) Tendon transplantation is of great value in cases where nerve suture is impossible, or has given a result not entirely satisfactory.

La Presse Médicale.

September 27, 1917.

Three New Cases of Rabies in Man.—Grenier de Cardenal, Legrand, and Benoit, refer to the six cases recently reported by Jourdran and Marchand, in which the disease was of the convulsive type with death within 48 hours in part of the material. There was but one case of the paralytic type in which death did not take place for five days. The bulbar syndrome was predominant, and hyperesthesia was absent. There was complete lucidity and in two cases euphoria alternated with depresssion. In these cases there was wide departure from the classical type in which a stage of excitation is followed by a paralytic stage, the first-named being attended by hallucinations and maniacal excitement. The material of the present authors likewise shows departures from type. One case is given in detail. A mobilized man of 34, in charge of horses, gave no history whatever of a dog bite. There were no prodromes. After his usual breakfast, eaten with relish, he complained, toward noon, of a headache, and refused both food and drink. Later he vomited and lay down. A medical man made a diagnosis of angina. Next morning he made grimaces and had spasms of the masseters and pharyngeal muscles. The pulse showed notable instability, and the pupils were unequal. Despite the failure of characteristic symptoms a diagnosis was made of tetanus, in part because of his occupation (hostler). Headache and vomiting became so prominent that meningitis was suggested and lumbar puncture made with negative result. Mental excitement now appeared in paroxysms alternating with intervals of quiescence. By a coincidence the proffer of a glass of water made the diagnosis, as a typical hydrophobia crisis was induced. Sensitive-sensorial hyperesthesia appeared, and became intense. Taken to the neuropsychic clinic, he did not seem very ill, was able to undress himself and even passed a quiet night. In the morning he rose and dressed himself, but a crisis of excitement developed with vomiting. He kicked against the door, upset the furniture, and scattered the bed covers. The features, haggard, showed both fear and anger. Respiration seemed

labored and there was oppression about the heart. He answered questions rationally, but did not seem to have complete insight into his condition. A proffer of water was not followed by a crisis, but there was an apparent inability to swallow. After the attempt he coughed and vomited. Later he developed convulsions in the extremities and facial muscles; then assumed a fixed attitude and died in syncope on the third day of his illness. Autopsy was very largely negative, save for cerebral hyperemia. Diagnosis was confirmed after studies of the cerebrum and bulb. The second case in a woman of 50 ended in death within 48 hours, while the third occurred in a girl of 12 and likewise pursued a fulminating course. The Pasteur treatment had been refused from fear of the punctures. The disease began at 5 in the morning, with inability to drink. Delirium soon developed, followed by a prolonged stage of fainting attacks and vomiting. Death occurred in syncope after an illness of only 12 hours. In cases two and three there was a history of bites by dogs known to be rabid. In none of the cases was there a prodromal stage. Bulbar symptoms dominated the picture, while hydrophobic spasms were present only as isolated phenomena. The average duration of the disease was about 35 hours, and death in all cases occurred in syncope. In the absence of history of a dog bite diagnosis is extremely difficult, and in the first of the cases but a single hydrophobic spasm is recorded. Among possible false diagnoses are a local throat affection, tetanus, meningitis, acute mania, delirium due perhaps to infectious disease, etc.

Correspondenz-Blatt für Schweizer Aerzte.

September 29, 1917.

Atypical Case of Chronic Farcy.—Lutz reports a case of this affection of so unusual a type that it escaped diagnosis for years. It was once reported as a hemorrhagic, papulo-bulbous, and ulcerous eruption of hematogenous origin. The patient was a woman, which fact may have helped to obscure the diagnosis. The peculiar joint symptoms were suggested, but the subcutaneous abscesses of the typical case were absent. The first lesion appeared on a finger and all the lesions were limited to skin and mucosæ. A papule would appear with a hemorrhagic center, would enlarge, and perhaps heal with a pigmented trace, or instead, go on to form an ulcer of a necrotizing character. Whether by extension or confluence, large ulcerous areas were formed. Some ulcers healed with keloidal scars. The lesions appeared to come out in successive crops, and a gram negative bacillus was found in the blood during one of these crises. Improvement in the case was attributed to neosalvarsan injections, but the source of the mischief was not controlled. The Wassermann and tuberculin tests were negative throughout. There was never much systemic reaction (subfebrile temperature at times), and death was due to extensive ulceration in the pharynx and larynx. An elaborate histological and bacteriological study, including animal inoculation, was negative. Only by exclusion apparently was the diagnosis made for farcy alone is able to produce such lesions. The author believes that infection occurred in the finger. How the lymphatic system escaped so thoroughly is not even debated. The viscera were all intact.

Case of Blastomycosis of the Skin.—Dösseker describes a condition extremely rare in Switzerland in a patient aged 46 years, who had no illnesses since childhood. It had appeared 8 years before with lesions suggesting pustules, or boils, in the left axilla. After six months of futile therapy the entire lesion-bearing area was excised. After three years' respite the lesions appeared in the opposite armpit, and some months later in the groins, extending directly to the scrotum and anal furrow. There was at no time any ulceration, although the continuous secretion had a very offensive odor. Gradually the general health showed impairment. Patient had never been out of his home land for any length of time. Professor Jadassohn made the diagnosis, by exclusion, of a mycosis. The lesions could be characterized as neoplasms in the lower folds, while in the axillæ they were distinctly inflammatory. In both localities, however, there were large numbers of what might be termed minute fistulæ, which furnished an extensive secretion. Biopsies and bacteriologic and inoculation studies were quite negative, and especially were there no evidences of mycosis. Persistent following up of the secretion, however, eventually led to obtaining a pure culture of yeast cells. Intensive and prolonged iodine treatment was unavailing, as was the use of yeast vaccines, and the *x*-ray. For some reason, however, the disease seemed to have been checked; the general health improved, and yeast cells could no longer be cultivated from the secretions. Naturally the author was none too certain that these bodies had caused the disease, although the large numbers present at one time could hardly have been mere saprophytes. A study of blastomycosis as described by Busse-Buschke in Europe and Gilchrist in America seems to leave little doubt as to the nature of the author's case.

Revue Médicale de la Suisse Romande.

September, 1917.

Relapse After Goiter Operations.—Sarkissiantz admits that his material is rather small for generalization but gives his conclusions for what they are worth. They pertain to the nodular forms and are as follows: Anastomoses between trachea and isthmus and those originating in the distribution of the esophageal arteries—even after ligature of the superior thyroid artery—assume sufficient vitality for the remains of the thyroid after ligature of the four thyroid arteries and even in addition of the fifth. But ligature of all of these vessels will not guarantee against a socalled pseudorelapse. Ligature in fact provokes a considerable proliferation of connective tissue and perhaps at times of a vascular neoplasia which makes a second operation hard to control and requires laborious dissection as compared with the ordinary operation for enucleation, although repair may be proportionately accelerated. A simple but thorough unilateral operation although deficient in cosmetic result gives a better prognosis against recurrence. Combinations of ligatures of various plans do not give divergent results. Multiple ligatures in enucleation operations, perhaps because of the resulting proliferation of connective tissue, predispose to an unwelcome type of recurrence which has an increased tendency toward cyst formation of a conglomerate character.

Photoanthropometry for the Control of Child Growth.—Jeanneret and Messerli refer to the need of measuring the growth of the various segments of the body. That introduced by Godin involves measurements and graphic representation and requires much time and precision. Much of the method has to do with circumferences and generally speaking there are many opportunities for subjective error. Weissenberg also takes ordinary anthropometric measurements of segments and uses tables of figures but no graphics. The authors have found the photographic method far more simple while the personal equation is eliminated. Any photographic technician can take the pictures and schematics are not required. The photographs are reproduced on grilled paper, the squares measuring 1 cm. life size, but reduced to a tenth on the photograph. To illustrate the growth increase one half of a photograph at a given period is placed on contact with the opposite half of a picture taken at a subsequent period. By this method the most trivial peculiarities of growth are brought out. Thus we note that the nipple at 16 was 6 cm. higher than at 15; while at the navel line the difference was but 5 cm. The relation between the tip of the medius and the level of the thigh was a constant. There was a difference of not more than 1 cm. in the height of the pubes, although the total gain in stature was 9 cm.

Prolonged Survival after Operation for Cancer of the Cervix.—Thaler reports on the fate of 70 women who had lived 5 years after Schauta's vaginal hysterectomy. In a period of 10 to 15 years after operation 60 women were still living and well. Hence he would not ray the operable case.—*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

American Public Health Protection. By Henry Bixby Hemenway, A.M., M.D. Author of The Legal Principals of Public Health Administration, Etc. Price, $1.25 net. Indianapolis: The Bobbs-Merrill Company, 1916.

Dr. Hemenway has dedicated this book to the Women of America, as "the power behind the throne." He goes on to state that "in the past they have done much to assist in securing better conditions; but amateur sanitarians should not themselves attempt to determine administrative policies or legislative provisions. In the place of trying to decide how dairies should be managed they should make sure that a competent health officer is employed, and then follow his leading." In connection with this good advice should go, hand in hand with the training of the women of America, a course of study in public health and this book would make an excellent member of the reading course.

It outlines the present methods of public health administration, with the good and poor points clearly shown, the National health agencies, the lack of attention paid to this important work of limitless value in the medical schools, medical inspection of schools, organization of health departments, and the preparation of health officers.

If all women all over the land could be made to realize the tremendous importance of the work Dr. Hemenway is so earnestly calling attention to, and which he has so splendidly outlined in his book, public health administration would develop so rapidly, the standard of general civic health would be so quickly changed, that the progress made in this direction in the past ten years would be but as child's play, compared to the results that could come were the women of the land fully awake to the possibilities of this throbbing, life-giving subject.

The time is fast coming when women, whether they wish it or not, must assume control of matters vital to the community and the world at large. The men have left this work in their hands. Hands and minds unaccustomed to think and work beyond the home must now come forth to learn quickly, and to assume responsibilities and positions unheard of in the lives of the women of yesterday; soon to be but a common occurrence in the lives of the women of the Now.

Dr. Hemenway has appealed to the true, the right note in the preface of his book. Back of him must stand the medical profession, and beyond that the United States, in this big effort of the women to attain national results never known in the world before.

The Diagnostics and Treatment of Tropical Diseases. By E. R. Stitt, A.B., Ph.G., M.D., Medical Director, U. S. Navy; Commanding Officer and Head of Department of Tropical Medicine, U. S. Naval Medical School; Graduate, London School of Tropical Medicine; Professor of Tropical Medicine, Georgetown University; Professor of Tropical Medicine, George Washington University; Lecturer in Tropical Medicine, Jefferson Medical College; Member, National Board of Medical Examiners; Member, Advisory Board, Hygienic Laboratory; Formerly Associate Professor of Medical Zoology, University of the Philippines. Second Edition, Revised and Enlarged; with 117 Illustrations. Price $2. Philadelphia: P. Blakiston's Son & Co.

The new edition of this useful little book contains four new chapters, in addition to several new paragraphs, as well as much careful revision of the original matter. The new chapters are those on typhus fever, spotted fever of the Rocky Mountains, special problems attaching to diagnosis in the tropics, and the diagnostic value of clinical manifestations from the side of the cutaneous system and organs of the special senses. In spite of its small size, this volume is of more than ordinary value. It is intensely practical, is well arranged and written, and is thoroughly up to date. The second part of the book, which deals with the diagnosis of tropical diseases, is packed full of just such information as the busy practitioner stands in need of. Although this edition is larger than its predecessor by more than one hundred pages, it still remains a pocket manual. Its very moderate price is an additional attraction in these days of "high prices."

Modern Dietetics. Feeding the Sick in Hospital and Home. With Some Studies on Feeding Well People. By Lulu Graves, Dietitian Lakeside Hospital, Cleveland. Price, $1.00 net. St. Louis: The Modern Hospital Publishing Company, 1917.

This book is a compilation of papers that were written by the author and published in *The Modern Hospital*, a monthly journal devoted to the interests of hospitals, sanatoriums, and other institutions of like character. It is truly scientific in the material offered, and has the added advantage of being written in a style sufficiently popularized to meet the need of readers of all types who are interested in foods, both from the physiological and chemical standpoint. Added to these, the author has intelligently handled the management of food for the many as well as the few, well or ill. Many recipes are offered, and it would seem to the reviewer that the book should have a place on the shelf of the housewife who has had sufficient college training to appreciate the value of just such working knowledge as Miss Graves has presented in these 202 clearly written and valuable pages. The book naturally offers itself as a fund for reference in connection with college courses on this and allied subjects.

The Prescription, Therapeutically, Pharmaceutically, Grammatically and Historically Considered. By Otto A. Wall, Ph.G., M.D., Professor of Materia Medica, Pharmacognosy and Botany in the St. Louis College of Pharmacy; Member of the Committee for Revision of the Pharmacopœia of the United States, 1880-1890 and 1890-1900; Second Vice-President of the Convention for the Revision of the United States Pharmacopœia from 1900-1910; Presiding Officer of the United States Pharmacopœia Convention of 1916; one of the Authors of the "Companion to the United States Pharmacopœia"; Author of "Handbook of Pharmacognosy," "Lessons in Latin," etc. Fourth and Revised Edition. St. Louis: C. V. Mosby Company, 1917.

The art of prescription writing is almost lost in this country, notwithstanding the fact that the knowledge of how to write a prescription correctly is extremely useful to the medical practitioner. Dr. Wall in the work before us enters into the subject thoroughly, and his book should prove very serviceable to members of the medical profession.

Massage, Its Principles and Practice. By James B. Mennell, M.A., M.D., B.C. (Cantab.), etc. Medical Officer, Physics Therapeutic Department, St. Thomas' Hospital; Civilian Medical Officer in Charge of the Massage Department, Military Orthopedic Hospital, Shepherd's Bush. With an Introduction by Sir Robert Jones, C.B., F.R.C.S., Colonel R.A.M.C., Inspector of Military Orthopedics. With 135 illustrations and an appendix. Price, $3. Philadelphia: P. Blakiston's Son and Co., 1917.

Massage, that is massage scientifically done by trained men and women under the supervision of surgeons, has naturally been very largely employed during the present war. Its value as an aid in the rehabilitation of disabled soldiers is obvious and has been established on a firm basis. Sir Robert Jones, certainly one of the first authorities on orthopedic treatment in the world, points out in an introduction to Dr. Mennell's work that in order to obtain the best results from massage the masseur or masseuse must cooperate loyally with the surgeon, and that when this close alliance is maintained, massage may be successfully employed as a preliminary to, as a concomitant with, and as a sequel to active surgical treatment. Massage may be of diagnostic value as a preliminary to surgical treatment, and may be employed to alleviate pain, reduce edema, assist circulation, and promote the nutrition of tissues.

As a sequel to operative treatment, it serves to restore the nutrition of tissues, and initiate the patient into an appreciation of muscle sense and movement lost by months of disuse following a severe septic injury, thus paving the way to recovery of voluntary muscle action, which is the ultimate aim of all orthopedic treatment. The writer of the book is well versed in scientific massage and has produced a work on the subject, which is especially apropos at the present time. The book is excellently illustrated and is in every respect an eminently satisfactory text book on massage.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 1, 1917.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE subject of the evening was "The Study of Crime and the Criminal from the Point of View of Modern Psychiatry."

Dr. WALTER B. JAMES, in opening the meeting, said that there were very few branches of medicine in which more advances had been made in recent years than in psychiatry and in few other lines had advances been made that promised to do more for the relief of the people from the burden imposed upon them by the criminal and the delinquent than in psychiatry. There was one branch of this subject that had been receiving special attention, and that was the method of handling the delinquent. To this Dr. Healy, who was to be the first speaker, had been devoting his attention for a number of years, first in the Juvenile Delinquent Home in Chicago, where all who had seen his work were impressed with its great value to the community, and later in Boston, where he had been called to take charge of the Judge Baker Foundation and organize a somewhat similar work.

The Study of the Juvenile Delinquent.—Dr. WILLIAM HEALY of the Judge Baker Foundation, Boston, made this address. He said that with his invitation to present his subject to the Academy of Medicine he had received specifications for his address. These stated that the address was to be informal, was to tell what they were doing, why they were doing it, and what their results were. He would try to follow orders, but he could not keep the points which he had been called upon to discuss separated. To put it in the simplest terms, they were studying from the psychological standpoint the conduct of numbers of individuals. They were doing this because such a study was desperately needed. He had found at the beginning of his work ten years ago that a little work along these lines had been done in France, but nothing in this country. He had become interested in this subject because from the cases seen in the clinics he felt that there were defective mental conditions which caused conduct disorders which thus far had not been recognized for what they were. He felt that perhaps if these causes were understood, they might be able to forfend the careers of certain individuals who seemed destined to follow a criminal career. In order to study the problem they were obliged to study the offenders as they appeared in the courts, because the average case was not available for study until he came into court. They were now studying the cases in court because they were so imminent and the courts were failing to properly and efficiently handle the problem which the juvenile offender presented. An English prisoner, writing in the *British Medical Journal*, in 1903 or 1904, stated that there were 186,000 convicts in English prisons and that 100,000 of these had been convicted before. The same condition prevailed in this country, though unfortunately we had no national statistics to show it. The statistics at Sing Sing Prison showed 60 per cent. of recidivists. They were dealing with the juvenile offender rather than the confirmed criminal for several reasons: (1) They got the juvenile offender earlier and were thus able to ascertain more with reference to his home environment, his heredity, and his development, so that scientifically it was more worth while to study the offender at an early age. (2) Nearly all professional criminals had picked their careers during childhood. Dr. Glueck, in recording the life history of criminals, showed that a large percentage of criminals had chosen their careers during adolescence or mid-adolescence. (3) They had studied the young offender because they could do more with him. By directing him and giving him a favorable environment he might be benefited physically and mentally and might thus be less crippled in his career. They were studying more particularly the mental life of the young offender, because it was the mental life that lay back of misconduct and, of course, of conduct in general. They were studying the juvenile offender from the standpoint of psychology rather than of psychiatry. He hesitated to use the term psychiatry because he did not want to give the idea that the average individual guilty of misconduct was mentally diseased, for he knew that many of them were not the victims of actual mental disease. By a study of the subject's mental imagery one would find that the individual held in his mind certain definite pictures of conduct, certain ideals of things to be reached out for, and that he had as a result certain impulsions or obsessions based on his mental imagery, but this was not to be thought of as mental disease. Again an individual might have certain abilities which denied ordinary and legitimate satisfaction led to a maladjustment of the individual to his environment and to misconduct. With this conception in mind it was evident that the field of study presented by the juvenile delinquent transcended that of psychiatry which dealt only with disease entities and was satisfied with word classifications. On the other hand, they were thinking of practical ways of helping the individual in his particular trouble, in the present instance, his misconduct. They were studying the physical makeup of the young offender because of its bearing on his mental life and on his misconduct. In the same way they went into his environment because certain unsanitary conditions in his surroundings might have a deleterious effect on his mental life and conduct. The mental impressions which an individual received from his mother or from his own mind when in a state of vacuity were most important in making up his conduct. Dr. Healy then showed that the psychological life in institutions had a very deleterious effect on the inmates. It was to be recalled that "an empty mind is the Devil's workshop." When the inmate of an institution had nothing else about which to think he turned his attention to planning what he would do when he regained his liberty, and these plans were usually for a continuance of his criminal career. Another point they were studying was heredity. In this field they were feeling their way very carefully and had avoided drawing conclusions. They were making their studies from the medical and psychological standpoint and focussing them on what lay directly at the basis of misconduct. The first thing they endeavored to find out was the facts in the case, and then they were in a position to consider therapeutic measures. They had the records of thousands of individuals studied in this way. He cited the following instances as an illustration. A certain boy was brought into court and the lawyers argued that because of the acts he had committed he must be insane. He was placed in an institution for the feeble-minded. He soon committed arson and was then placed in the house of correction. He behaved so badly there that he was transferred to the men's department. This boy had never been happy. The speaker had known him for nine years. As a child he had had middle-ear disease, did not hear well, and did not do well in school. He had always been unhappy and had never had what he wanted. It was found that he had considerable artistic ability. He was given a set of paints, took a course in drawing and painting, and for the first time in all his life he had the human satisfaction he demanded. After that he gave no further trouble. That boy was not insane, but under ordinary conditions no one would ever have found what his mental content actually was and how to readjust him. These juvenile delinquents were of no one type and there was no one set method of examination; each case must be individualized. They were simply beginning to handle a big human problem that was of vast importance to society and with great possibilities for the future, not only with reference to a scientific understanding from the pathological side, but with possibilities of obtaining a better understanding of the ways for developing the potentialities of the normal individual. Psychiatry and psychology were sciences of very recent growth. A passing judgment rendered as the result of giving a few tests, when one thought of the brain with its five million cells and the mind with its thousand intricate recesses which were just beginning to be explored, could be worth little; the psychologists realized this themselves, and if the psychiatrists would take into consideration the more normal phases of the human mind their opportunities of assisting in the development of a big human service would be very much greater.

The Study of the Prison Inmate.—Dr. BERNARD

GLUECK spoke on his experience in the Psychiatric Clinic at Sing Sing Prison. He said that Dr. Healy's address had given him a little optimism, much needed after a year or so spent in an institution like Sing Sing. He did not disagree with Dr. Healy as to the possibility of reconstructing the lives of these people, but one was apt to become pessimistic about the situation when he saw case after case committed to prison with such extremely bad careers back of them, and especially so when there was so little opportunity to study and handle them individually. It was felt when the Psychiatric Clinic was established at Sing Sing that it could be of some help to the administration if a clear definition of each individual delinquency could be found, a clear outline made of the forces that had been at work in making the criminal what he was at the time he was admitted to prison. It was believed that they would thus find the way to attack the problem more successfully in individual cases. Hence the first function of the clinic was definition. There was frequently considerable agitation on the subject of prison reform, but most people had no conception of the difficulties of prison management itself and the attaining of better conditions. Many attempts in the direction of reform had been made and given up as failures. Men in charge of prisons knew the difficulties which the problem of handling prisoners involved, but the community outside, that provided the facilities, seemed indifferent to the actual facts. Dr. Glueck said he believed there was some hope of changing the mental attitude of the prisoners toward life in general, but that was a matter of individual therapy. The question to be solved was that of giving the prisoner a different outlook on life, especially after leaving prison. The charts exhibited showed that the effort at definition had been successful to some extent. They had collected a great deal of information with reference to the past histories of the inmates. It was shown that considerably over one-half of the prisoners were recidivists; some of them had been imprisoned a number of times before. The percentage showing bad heredity and subnormal physical and mental conditions was also shown. It must be remembered that in Sing Sing they were dealing with a highly specialized group of people. Dr. Healy got his cases at the beginning of their antisocial careers; the speaker had been seeing them at the end results. It seemed that a long criminal career served to deteriorate these men, and their mental condition was very difficult to change. Dr. Healy had called attention to the physical conditions that lead to abnormal mental states; of course, as was well known, the physical conditions at Sing Sing were not of the best and it was difficult or impossible to utilize the recommendations of the Clinic, particularly along industrial lines. Under better conditions, it could undoubtedly be of aid in discovering the special aptitude of individual prisoners and of assistance in placing them in more suitable occupations. Time should not be wasted in trying to educate prisoners who were not educable, for in some of these adult cases no progress could be made in this direction. The Clinic, however, hoped to be of more use along these lines after the new prison was built. Much more might be accomplished if, when a man left prison, he had the opportunity to consult someone who knew his case thoroughly and who would guide him when he came to stressful points in life. In this way conflicts with the law might in many instances be prevented. This was a possibility that the new prison offered. If the Clinic continued to meet with the cooperation it had thus far received from prison people, even more useful work might be done in the future than had been done in the past.

D. BULKLEY HUBBELL, Esq., of the New York State Commission on New Prisons, said he had learned early in life that it was well not to dispute with the doctors; perhaps the fact that one of them was his father might have aided him in reaching that conclusion. When he received the invitation of the honored president of the New York Academy of Medicine to take part in this discussion, he felt that the invitation like that of royalty was equivalent to a command, consequently he acquiesced in it with becoming humility. He wished to say that he had never in his life undertaken a work which had been so fascinating as this work in connection with the Prison Commission, and he had served the State and City in various capacities. While on the Board of Education he had taken an active part in introducing the examination of school children for contagious diseases and in having teachers regularly examined for tuberculosis. In this work he had been ably supported by the doctors and they had likewise given him their support and cooperation when he was on the State Hospital Commission. When the New Prison Commission found itself confronted with the task of demolishing the old Sing Sing Prison, that monument of iniquity, and replacing it by a modern structure, he immediately turned to the doctors for assistance and advice. He claimed for himself sagacity when he selected Dr. James as the first member of his Advisory Committee. The speaker then paid a glowing tribute to Dr. James for his unflagging zeal and the value of the expert advice which he had contributed to the solution of their problems. He also commended Dr. Glueck's work at Sing Sing and said that as a result of the cooperation from these various sources a new prison had been planned which would be a clearing house for the State, where men would be classified by the methods demonstrated this evening. He felt that now that the facts in relation to the causation of crime were becoming known they were in a fair way to solve some of the problems which had baffled them in the past. The main point it seemed was to get the criminal when he was young, and to train him in such a way that his criminal tendencies would be overcome. The indeterminate sentence would be of some assistance in controlling and keeping under observation certain criminals; the health of such individuals would thereby be improved, they would be given the opportunity for reformation, and at the same time they would be kept from preying on society.

Hon. GEORGE W. WICKERSHAM said that the only qualification he had for speaking on this subject was his interest in the administration of justice. In this direction little progress had been made in a century and a half. Thus far they had made little progress in gaining a knowledge of the facts upon which justice must be based. He was interested in the science of psychiatry because it was a scientific method, its best point being a relentless investigation of facts. All science must be based on a ruthless search for truth. In Sing Sing Prison they had been studying crime and the criminal to a greater extent than anywhere else in the United States. They had searched for the facts in relation to the cause of crime, and they must place these facts before the public before they could hope to change existing methods of dealing with the criminal. In determining the consequences of crime one should be guided by the condition of the offender. Crime must be dealt with from the standpoint of prevention and treatment. The point that stood out prominently in the charts they had been looking at and that Professor Kimball and Judge Olsen of Chicago had emphasized was the necessity of preventive treatment through an effort to supply the child with an environment which did not permit him to become a criminal, but saved him to be an asset of the State, for there was no greater asset to the community than the lives of its children. There was an abundance of legislation, some wise and some unwise, but whether it was wise or unwise, it showed that the public conscience had been quickened in reference to the value of the child. This was shown in the establishment of children's courts, and out of this move good results must come. This reaching out after human justice held much promise for future years. Mr. Wickersham said he did not think much could be done for the old offender; as a rule, he was unfit to live in organized society. In dealing with him the indeterminate sentence offered some relief, but it might be many years before the economic value of this method would be appreciated. The second point that struck him in the statistics presented this evening was the large percentage of native born criminals. We had been flattering ourselves that a large percentage of crimes was committed by foreigners. It seemed from these statistics that it behooved us to give ourselves more concern for the native born.

Dr. AMOS SQUIRE, physician to Sing Sing Prison, said he was glad of this opportunity to state that he was in favor of, and in sympathy with, a study of the criminal from the point of view of psychiatry, or any

other point which would give promise of lessening crime, or improving the mental and physical condition of the criminal. This applied not only *after* he got to prison but more particularly *before* he was sentenced by the Court. One week ago today a man was brought to Sing Sing prison for a term of four years, who gave a history of mental disturbance covering a period of three years. Had this man been examined, it was the speaker's opinion that he would have been sent to Matteawan for treatment and not to Sing Sing prison for punishment. Dr. Squire said that not being a psychiatrist he would not discuss the subject from that standpoint in medicine, but would simply say a few words about his experiences with criminals, as physician in charge of Sing Sing prison. No one could be there long before being impressed with the fact that a large percentage of their prison population were below the average in mental and physical condition. Dr. Glueck had stated in his report that about 59 per cent. were below par in respect to their mental and physical condition. He had been impressed more and more every day with the fact that the treatment of the criminal was a medical one and that the only hope of success lay in a careful, thorough, and systematic study of each individual case, and not in a haphazard or slipshod examination. It had been their custom for some time past to make a careful physical examination of every new admission. Whenever they found an inmate suffering from any physical disability which could be corrected by surgical interference this fact was noted on his card and at the earliest possible moment the condition was corrected. Although he had not seen the criminal as yet that had what might be called the general criminal physique, he did believe that there were physical conditions, peculiarities, and ailments that had a very direct bearing on prisoners or delinquents and should be corrected, if possible, not only to improve the inmate's health but also not to stand in the way of his social success. Among these ailments which concerned the causation of delinquency were the following: (1) Ocular ailments, which led to eyestrain, defective vision, irritability, and headaches had their influence on the education and other interests of the subject. (2) Teeth. The examination of the inmate's teeth was a part of the regular procedure. This year $500 had been appropriated for the services of a dentist and they now had a visiting dentist who spent one day a week at the prison, but their crying need was for a full time dentist. Seventy-five per cent. of the inmates needed the services of a dentist. All physicians realized that carious teeth were a menace to the general health and stood in the way of social achievements. All men upon admission to a prison should be furnished with a toothbrush and other toilet articles, a need which the speaker had mentioned in his report just completed. (3) Nose and throat, adenoids, tonsils, and nasal obstructions had received attention, as they believed that they were frequently the cause of physical weakness and general malaise. During the year ending July 1, they removed 40 tonsils and performed 41 submucous resections. (4) Syphilis. During the year, 928 inmates were admitted and 20 per cent. of them responded positively to the Wassermann reaction. How far this disease was a factor in causing delinquency was a question to be studied. Every man who entered Sing Sing with a positive Wassermann was the next day placed on anti-syphilitic treatment. With the effect of alcohol and drugs on delinquency all were familiar, but it appeared to him that they were getting more prisoners with the drug habit than formerly. Last week out of about 15 admitted three were suffering from the drug habit. As the medical staff of Sing Sing Prison consisted of an assistant and the speaker, together with an oculist and a genito-urinary man spending a portion of a day each week gratuitously, it might be seen that they were unable to give the men the individual attention their physical needs required. Last year 678 minor and major operations were performed and 15,707 prescriptions written. This was no one man's job, but needed the combined efforts of the best talent in all branches of medicine. They were looking forward now to the building of a new prison hospital provided with complete modern equipment, and when that was obtained their work would be coordinated and better results would follow.

Stated Meeting, Held November 15, 1917.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Anniversary Address: The Origin and Nature of Life.—HENRY FAIRFIELD OSBORN, LL.D., President of the American Museum of Natural History, delivered this address, in which he presented a new energy conception of evolution, according to which all life consisted in the capture, storage, and release of energy. He reviewed the various theories that had been advanced to explain the origin of life—the creative, the vitalistic, and the materialistic or mechanistic—and argued that all these theories, including the natural selection theory of Darwin, failed to explain the unquestionable facts of evolution. He then presented his theory which he said was better supported by reason and modern scientific data than any of the theories thus far advanced. Descartes had led all modern natural philosophers in perceiving that the explanation of life should be sought in the physical terms of motion and matter. The more modern scientific opinion was that life arose from a combination of forces preexisting in the cosmos. To hold the opinion that life did not represent the entrance of either a new form of energy or a new series of laws, but was simply another step in the general evolutionary process was certainly consistent with the development of mechanics, physics, and chemistry since the time of Newton. Every advance in the quest as to the nature of life had been in the direction of a physicochemical rather than a vitalistic explanation. Thus far all theories of the origin of life, had failed because investigators had started from the tremendously complicated organism and tried to work back to a simple organism. He had attempted to reverse the method and had tried to imagine the earth before the development of life, when there was nothing but the bare rock, soil, water, and air. So far as the creative power of energy was concerned one was on sure ground; in physics energy controlled matter and form; in physiology function controlled the organ; in animal mechanics motion controlled and in a sense created the form of muscle and bones. In every instance some kind of energy or work preceded some kind of form, rendering it probable that energy also preceded and controlled the evolution of life. Lavoisier had immensely advanced science when he discovered the laws of action and reaction and the conservation of energy. Action and reaction referred chiefly to what was going on between the parts of the organism in chemical or physical contact and were subject to two dynamic principles. Interaction referred to what was going on between material parts which were connected with each other by the two great dynamic principles alone without a knowledge of the structure that connected the interchanging parts. As an illustration of this, one might cite the interacting nerve impulse darting from a microscopic cell in the brain which gave rise to a powerful muscular action or reaction at some distant point. An interacting enzyme, hormone or other chemical messenger circulating in the blood might profoundly modify the growth of a great organism. Now the central theory to be developed was that every physicochemical action and reaction concerned in the transformation, conservation, and dissipation of energy produced also, either as a direct result or as a by-product, a physicochemical agent of interaction which permeated or affected the organism as a whole or affected only some special part of it. Through such interaction the organism was made a unit and acted as one because all of its parts were correlated. The functions of co-ordination, balance, co-operation, compensation, acceleration, retardation of actions and reactions were all examples of interaction. It was the peculiar evolution and elaboration of the physical principle of interaction which distinguished the living organism. Thus the evolution of life might be rewritten in terms of visible energy as it had been written in terms of visible form, namely, inorganic environment, the sun, earth, air, and water. There were present in the inert earth the elements, hydrogen, oxygen, nitrogen, carbon, phosphorus, sulphur, potassium, calcium, sodium, iron, etc. The structure and form of life depended upon the combination of these elements. There was also the sun, a source of heat, light, and other

forms of energy, though it was possible at that early date that there might have been some heat generated in the earth itself. Thus the earth, air, and water contained all the elements known to be essential to bacterial or prechlorophyllic life. An initial step in the origin of life was the bringing together of these elements. Molecules of hydrogen, nitrogen, carbon, and oxygen assembled into protein. All the functions of life were due to the motions, actions, reactions, and interactions of these. The motion of even one molecule gave heat and sound. But there were much finer forms of motion than those of the molecule, namely, those of the atoms of which the molecules were composed and those of the electrons which drove the atoms. In these one arrived at pure energy. If one took the smallest visible grain of sugar it contained 100,000,000 molecules, 300,000,000 atoms, and 300,000,000,000 electrons. These electrons travelled with velocities of 10,000 to 100,000 miles a second. We thus had ionization causing action and reaction and catalysis or interaction, which was the term applied to all phenomena of motion not explained by action and reaction. An ion was an atom or group of atoms carrying an electric discharge, and it possessed the principle of electric attraction and repulsion. The molecules of the nonmetallic elements, carbon, oxygen, nitrogen, and phosphorus, exerted a strong attraction for the negative electrons and gave off negatively charged ions which moved toward the anode. The molecules of the metallic elements hydrogen and the salts of potassium, sodium, calcium magnesium, and manganese exerted relatively weak attraction and gave off positively charged atoms. The atoms were, under certain conditions of light and heat, torn apart by their electrons and recombined into other molecules. Sugar, for instance, served as an example of the storage of energy. A molecule of sugar contained 12 atoms of carbon, 22 of hydrogen, and 11 of oxygen. It was apparently inert until taken into an animal, when this latent or potential energy was released and turned again into the heat and motion of the body. Thus we would have a cycle of the capture, transformation, storage, and release of energy, all of which came ultimately from the sun, either its light or heat. The simplest organism of which one could conceive was such an energy seeker.

The theoretic evolution of the four complexes of energy might be conceived somewhat as follows: (1) The organic environment, energy, and matter as seen in the sun, earth, air, and water, forming an entirely orderly system, held together by gravitation, moving under Newton's laws of motion and subject to the laws of thermodynamics. (2) What we called organism, a union of the external and internal adjustment of energy. In the course of the evolution of life every law and property in the physicochemical world was turned to advantage, every chemical element assembled in which inorganic properties might serve organic functions. There was an immediate or gradual separation of the organism into two complexes of energy; first the energy complex of the organism, perishable with the life of the individual, and, second, the germ, or hereditary substance, which was perpetual. (3) The hereditary germ in some respects bore a likeness to latent or potential interacting energy, while in other respects it was entirely unique. The supposed germ energy was not only cumulative, but was in a sense imperishable, self-perpetuating, and continuous during the whole period of life upon the earth. (4) The energy complex of the life environment was a new factor which entered with the multiplication and diversification of individual organisms. Thus were combined three and possibly four complexes of energy, each of which had its own actions, reactions, and interactions. If a single name were demanded for this conception of evolution it might be termed the *tetrakinetic* theory in reference to the four sets of internal and external energies which played upon and within every individual and every race. In respect to form it was *tetraplastic* in the sense that every living plant and animal form was plastically moulded by four sets of energies.

As soon as the grouping of chemical elements reached the stage of an organism interaction became essential, for the chemical activities of one region of the organism must be harmonized with those of other regions. Here we had the action of a catalyzer or chemical messenger, which modified the velocity of any chemical reaction without itself being used up by the reaction. Catalysis had been proven to underlie the great series of functions in the organic world. In the human body such a catalyzer was an enzyme. It accelerated or retarded reactions in the body by forming intermediary unstable compounds which were rapidly decomposed, leaving the catalyzer (enzyme) free to repeat the action. It was imperative that life should have originated in the colloidal state because that state was more favorable to action, reaction, and interaction.

In the human body the secretion of the pituitary body served as an example of a catalyzer regulating and controlling growth. As a part of this theory of the origin and development of life one must also take into account that upon the resultant actions, reaction, and interactions of potential and kinetic energy in each organism selection was constantly operating wherever there was competition with the corresponding actions, reactions, and interactions of other organisms. In examining this theory of life the question also presented itself whether we might have here also the basis of an explanation of heredity. The origin of heredity offered quite as difficult a problem as the origin of life itself. It was quite possible that we had in the chromatin of the body cell the germ of heredity. Goodale's experiments by which he transplanted the testicular tissue of a cockerel into a hen and the ovarian tissue of the hen into the cockerel, and, as a result, found the sex characteristics of the hen appear in the cockerel and *vice versa*, served to show the action of the chromatin of the sex cells as a catalyzer and suggested the possibility that this chromatin might be the germ of heredity.

In closing Dr. Osborn said that quite possibly what had been said of other theories might be said of his theory of the origin of life: "What is true in it is not new, and what is new is not true."

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting Held October 23, 1917.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Severe Toxemia of Pregnancy of Hepatic Origin Treated by Transfusion.—Dr. A. J. RONGY reported this case. He stated that the patient was 37 years of age, a VI-para. Five of the children were living, the oldest being 19 and the youngest seven years of age. The patient was admitted to the hospital on February 4, 1917, at 11 P.M. At this time the cervix was dilated three fingers and she was having pains every ten minutes. The membranes had ruptured. The blood pressure was 155 mm. Prior to admission to the hospital the patient had been in bed for fifteen days and was attended by her family physician for a severe form of jaundice. She was deeply jaundiced at the time of admission to the hospital. At 12 o'clock the fetal heart sounds were heard in the right lower portion of the abdomen; at 3 P.M. the fetal heart sounds were no longer heard. At 3.30 P.M. the mother gave birth to a dead fetus. The urine showed a small trace of albumin, but no casts. The pulse, temperature, and respiration was normal at this time. The following day the temperature fell to 95° F., the pulse became slow and the patient showed signs of drowsiness, but she could be awakened. Toward evening she became very sleepy and gradually went into coma, respiration becoming slow. She continued in this condition during the entire night and the following day. Towards evening her condition seemed to be apparently hopeless. Dr. Rongy said he then suggested that the only treatment that might be of benefit to the patient was a direct transfusion of a large quantity of blood. The husband was chosen as the donor. Dr. Unger performed the transfusion at about 10.30 P.M. The patient at this time was apparently in a toxic condition. Gradually 20 c.c. of blood was taken from the patient and she was then transfused with 1,000 c.c. of fresh blood from the husband. While the patient was being transfused she began to show some signs of life but could not be awakened from her coma; this continued until 3 A.M. the next morning. At 4 A.M. she was fully awake and responded to ordinary questions. The morn-

ing following the transfusion her temperature was 102° F. and then gradually fell to normal. On the eighth day postpartum the patient had a chill and in a short time her temperature had gone up to 105°, pulse 140, and respirations 45. A blood culture was taken and examined by Dr. Lederer, who reported that the blood was positive for *Streptococcus viridans*, which grew both on plain and glucose culture media and plain and glucose agar media. The patient was still profoundly jaundiced, and her general condition was very poor. The treatment was mainly supportive. Between February 13 and February 19 the temperature ranged from 101° to 104° F. At times the patient became stuporous but she never fell into coma again. On February 19 her temperature fell to normal and remained normal until the day of her discharge, February 24. Clinically this case appeared to be a form of liver toxemia, with scarcely any involvement of the kidneys and, in the speaker's opinion, the case was not one of sepsis because at no time did the patient have a temperature until the second day post-partum. She was ill at home for two weeks before coming to the hospital and gradually became jaundiced. The area of liver dulness was diminished and there was probably a toxic substance produced by the pregnant state which affected the liver cells so that the liver could not functionate normally. Primary liver toxemia, the speaker said, was a very rare condition. He believed that every patient who showed evidence of jaundice during pregnancy ought to be watched very carefully and the proper treatment instituted if necessary. Transfusion in cases of toxemia of pregnancy would eventually, he believed, play a very prominent part in the treatment of this condition. If the patient showed evidence of toxemia she should be transfused at an earlier period of the toxic state, and in this way a severe toxemia might possibly be prevented. Our knowledge of this subject was very meager and it would be worth while studying this question more closely and in that way we might collect the accumulated experiences from many clinics which would probably give us information which would guide us in our treatment of these cases.

Ruptured Pus Tube and Diffuse Peritonitis.—Dr. ARTHUR STEIN presented this report. He stated that the rupture of a pus tube was a relatively rare occurrence, especially in non-puerperal patients, although perhaps not quite so uncommon as it was assumed to be. In order to extend their knowledge of this important complication it was desirable that all corresponding observations should be published. This was the reason he was giving his personal experience as well as the results of an investigation of the general literature. For a series of cases of peritonitis due to this particular cause we were indebted to Johanson, a Swedish operator, who, in 1912, reported 59 cases of peritonitis derived from pus tubes. A study of this series of cases showed that in certain cases traumatism of different kinds, notably gynecological or obstetrical, as for example in criminal abortion, entered into consideration as an etiological factor. The changes of the tubal walls were not uniform, but varied from very small interstitial abscesses through which the lumen of a pus tube might open into the peritoneum to small round ulcerations or simple softening and edematous infiltration of the wall. The seat of the perforation was located in one of the peritoneal surfaces of the tube, usually the middle or external portion. The size of the opening was variable and might not exceed a pin head in circumference. Although single, as a rule, the rupture was some times multiple and might involve both tubes. It was a noteworthy fact that perforated pus tubes were usually not much enlarged or distended. As a rule they had lost all communication with the uterus. In diffuse peritonitis from ruptured pus tubes the pus spread between the adjacent coils of small intestine, but the inflammation was not generalized over the entire peritoneal serosa and the case was accordingly not hopeless provided suitable and timely treatment was instituted. Rupture of a pus tube might also occur in connection with childbirth or abortion and culminate in peritonitis. Attempts at criminal abortion had been known to induce abscess formation in the tubal wall followed by rupture of the pus pocket and diffuse peritonitis. This patient, an Italian, 33 years of age, married, was admitted to the Harlem Hospital on July 6, 1917. Her family history was negative. She had two children, her confinements being normal. A previous curettage had been performed. Menstruation began at the age of 12 years and was of the 25, 30, 28-day type, lasting six days. The last period occurred on May 18, though she bled slightly in June. Her present illness began with pain in the lower abdomen a week before admission to the hospital. It had increased on the left side and the patient had vomited once on the day of admission. The patient was acutely ill, showing the usual symptoms of peritonitis, with a temperature of 102° F., pulse 120, and respirations 24. There was extreme tenderness and rigidity all over the lower abdomen. The abdomen was somewhat distended. The tenderness was so marked that no mass could be made out. The vaginal examination showed that the fornix was extremely tender. To the right of the uterus occupying the site of the adnexa was a tumor the size of a fairly large melon, extending nearly to the umbilicus. The surface was even and rather soft. Behind and to the left of the uterus, and partly filling out the cul-de-sac, was a small mass of similar consistency. The body of the uterus seemed imbedded between these two masses. Operation was performed on July 7, 1917. A median vertical incision was made below the umbilicus. Free pus was found in the abdominal cavity and a double tuboovarian abscess, the left one being ruptureh. A bilateral salpingo-oophorectomy was performed. Pus was all over between the coils of the intestines and the appendix was involved, one-half of it being necrotic. The appendix was removed and the abdomen closed. The patient made an uneventful recovery.

Early Ectopic Pregnancy Complicated by Appendicitis.—Dr. STEIN also reported this case. He stated that the patient was 26 years of age. Her previous history was negative. She had had one child, seven years ago. On the day previous to admission to the Harlem Hospital she was suddenly seized with severe pain in the right lower abdomen, accompanied by pains in the vagina. Her menstruations had always been regular up to the last time. She had finished her last menstruation about three weeks before. Examination showed bleeding from the vagina and the uterus somewhat enlarged and soft. There was marked tenderness extending over the right lower abdomen and up as far as McBurney's point. The right adnexa could not be definitely made out. There was no tissue discharged from the uterus. The patient was then transferred to the private building of the German Hospital for further observation. Being unable to make a definite diagnosis in two or three days, a probable diagnosis of ectopic pregnancy or subacute appendicitis was made, although the definite signs of appendicitis (rigidity of the muscles and rebound upon withdrawal of the hand after pressure) were not present. On the third day the patient had another attack of severe pain and operation was decided upon. A curettage preceded the laparotomy. Some apparently decidual tissue was removed. A transverse incision was made. Upon opening the abdomen the right tube was found to be about as thick as a thumb with blood oozing from the fimbrian end. There were marked adhesions with the omentum, and also with the appendix. The right tube and ovary were lying very high on the ilium. This location seemed to be the reason for their inability to locate and properly palpate the right adnexa. The right tube was then removed *in toto*, whereas the right ovary was left behind. The stump of the tube was secured with chromic catgut suture. The appendix which was adherent to the tube and was also subacutely inflamed and thickened with dilated vessels. It was removed and the stump buried with silkworm suture. The operation required twenty minutes.

Recurrence of Ovarian Carcinoma After Non-radical Operation.—Dr. HERMANN J. BOLDT presented this report because it served to emphasize the value of knowing what a previous operator's findings were at operation, in case a patient had had an abdominal operation done formerly. He said that undoubtedly this was a fact appreciated by every surgeon, and yet it was too frequently neglected. A goodly number of instances had come under his observation which proved the necessity of taking more careful histories and acquiring complete reports of the cases. The instance which he

would relate was the last he had met with and served as a good illustration. This patient had had a right ovariotomy done at Warsaw in 1903. On July 31, 1906, Dr. Boldt said he removed a left ovarian tumor. The patient, being then only 19 years of age and engaged to be married, he decided to retain a zone of seemingly functionating ovarian structure at the base of the tumor, particularly since the other ovary had been removed completely. She then married, and was later delivered by a well-known surgeon of New Haven by cesarean section. In September of this year she again consulted the speaker. An indefinite abdominal tumor in the lower part of the abdomen was present. The pelvis was filled with plastic exudate and the abdomen filled with ascitic fluid; its origin could not be ascertained. The seeming mobility of the abdominal tumor, despite the diagnosis of probable malignancy, would have justified an exploratory abdominal section if it had been impossible to obtain additional information. The patient gave none, but her companion, after she had left the consulting room, on questioning, told him that three months previously she had been operated upon at another hospital. On inquiry he learned that she was found to have an inoperable tumor and that the abdomen was closed. In referring to his notes of July 31, 1906, he found that he had noted that the tumor looked suspicious of malignancy. The pathologist's report he did not recall, nor was he able to find it on his file. He found a note, however, stating that he had seen the patient at a later date and that the patient was then menstruating regularly and was in good physical condition. The patient was then given a letter detailing all he knew about her case with the request that at the hospital to which he had requested her admittance the ascitic fluid be drawn off and *x*-ray treatment instituted. The surgeon in charge, from the result of physical examination, was led to think that the tumor might be extirpated. This was found to be impossible. The tumor was an adeno-carcinoma. Having seen one instance in which a cure resulted from Roentgen ray treatment in a similar condition, he believed that additional experimentation should be made with this agent.

Ruptured Uterus.—Dr. O. A. GORDON presented this specimen by invitation. The uterus had been ruptured during an attempt to induce abortion.

A Good Illustration of the Use of the DeLee Stethoscope.—Dr. FREDERICK C. HOLDEN made this presentation. He said that his object in presenting this specimen was not that it had any feature of special interest in itself, but because it afforded an opportunity to call attention to the use of the DeLee stethoscope, which was considered a help in obstetrical work. The specimen was a normal placenta and cord in which there were two knots in the cord at the time of delivery. The patient was a primipara, who had passed through a normal pregnancy and a normal L. O. A. labor. The interne in charge of the case was making repeated examinations of the fetal heart as the head descended. With the head on the perineum he suddenly was not able to hear the heart sounds which he had heard only a short time before. He immediately did a medial perinorrhaphy, and by an accouchement forcé was able immediately to deliver the child, which was in a condition of pronounced asphyxia, but was resuscitated with very little difficulty. In this instance one was impressed with the idea that the DeLee stethoscope was the means of saving this child's life. It was during the perineal stage when one was sterile which was the most important time to know the condition of the fetal heart, and yet many neglected to keep as close watch on the fetal heart as they should. One could not recommend this little instrument too highly, as it was a definite life-saver; it could be used without breaking the aseptic technique at a time when it was very important to know the condition of the child.

Metabolic Disturbances of Gestation.—Rissmann states that in Osnabrück there has been much less eclampsia and nephritis since the outbreak of the war. One primipara with albuminuria was found to be overfeeding. The use of mineral waters and vegetarian diet is commended.—*Correspondenz-Blatt für Schweizer Aerzte.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 22, 1917.

THE PRESIDENT, DR. J. BENTLEY SQUIER, IN THE CHAIR.

Resolutions on the Death of Dr. Brooks H. Wells.—The following resolutions on the death of Dr. Brooks H. Wells were presented by Dr. Charles Gilmore Kerley and Dr. John Van Doren Young:

"Dr. Brooks H. Wells was the son of the Rev. Edward Livingston Wells and Mary Huder Hughes Wells. He was born July 28, 1859, died July 6, 1917. After obtaining his preliminary education he graduated from the College of Physicians and Surgeons of New York in the Class of 1884, and served as Interne in the City Hospital on Blackwell's Island. Dr. Wells was Professor of Gynecology for many years at the New York Polyclinic Medical School and Hospital, likewise Associate Visiting Surgeon at the Women's Hospital, Consulting Physician to Beth Israel Hospital of New York City and the Brattleboro Hospital, Brattleboro, Vermont. He became a Fellow of the American Gynecological Society in 1902 and was elected one of its Vice-Presidents in May, 1917. He was also a Fellow of the New York Obstetrical Society, the American College of Surgeons, and the New York Academy of Medicine. He was also a member of the Medical Societies of the County and of the State of New York and the American Medical Association.

"In 1892 Dr. Wells became the Editor of the *American Journal of Obstetrics and Diseases of Women and Children*, and continued this work actively until his death. His editorial work is too well known among the readers of this journal to need any comment; suffice it to say that his success was founded upon sound judgment, a clear comprehension, an inherent sense of honesty, and a singleness of purpose. Dr. Wells demonstrated through all his work his firm belief that gynecology and obstetrics constituted one of the most important specialties, and his influence will long serve as a compelling factor in bringing this truth home to the profession. Dr. Wells was interested in the work of the Medical Reserve Corps and was recently commissioned a Captain in the Medical Officers' Reserve Corps. His patriotism and devotion to the work of this organization were characteristic of the man.

"Dr. Wells was keenly alive to the needs of our profession and a firm believer in organization for the accomplishment of good. This was demonstrated by his active interest in our Society, for when called to do anything for the Medical Society of the County of New York, no matter how much work was entailed, he was always ready. He felt his duty to the profession could only be discharged by a punctilious devotion to the work of the office to which he had been elected. That this devotion and ability were appreciated by the Society is shown by the fact that he served as Censor for four years, 1910-1911 and 1914-1915, and as First Vice-President in 1912 and President in 1913. His work and worth in the offices he held is best known to the members of the Comitia Minora, who served with him, but the whole Society had reaped the benefit of his effort and will continue to do so for many years to come.

"He has gone as have Drs. Richardson, Houghton, Townsend, LeFevre, and Huddleston, all devoted workers for the best interests of our Society; the ranks must close and their places be filled, if the work is to go on. They will not be forgotten; their example will inspire to greater effort and nobler achievement in the future.

"The Society extends to the family of Dr. Wells its deepest sympathy, well knowing that their loss is far greater than ours, but bids them remember that his work was always well done, and that he was honored and appreciated by our Society and the whole profession, a high reward indeed."

Results Following Operation in Seventeen Cases of Hour-Glass Stomach Due to Benign Ulcer.—Dr. WILLIAM A. DOWNES made this presentation. He said that he realized that this number of cases was far too small to justify positive statements, but the fact that 15 of them had been observed for an average of two and one-half years after operation, and one for more

than nine years, at least permitted an opinion as to the comparative value of the various operative procedures employed. There were 16 females and one male in the series. The average age was 39 years. There was one operative death, the patient dying from pneumonia on the sixth day after mediogastric resection. Well taken radiograms were of great value in establishing the diagnosis and in giving a fairly accurate idea of the relative size and shape of the pouches, the width of the channel connecting them, and the condition of the pylorus. This information was of great assistance to the surgeon in determining the operative procedure best suited to the given case. The one absolute requirement of any operation employed in the treatment of hour-glass contraction was that the symptoms due to obstruction be relieved. If at the same time the procedure adopted could include excision of the ulcer or the cicatrix of a healed ulcer, without too great risk, so much the better, but the fact must not be lost sight of that the great majority of these patients came to them on account of weakness due to inability to take or retain sufficient food. At least four operative procedures—gastroenterostomy, gastroplasty, gastrogastrostomy, and mediogastric resection—were available in the treatment of hour-glass contraction. To these pylorectomy should be added as the method to be adopted if the constriction was near the pylorus, thus forming a small distal pouch. Gastroenterostomy was the operation most generally used for the relief of this condition. It was employed in six of the writer's cases and was combined with gastroplasty in a seventh. This operation was indicated in those cases in which the constricted area was of wide extent, and in those in which adhesions prevented mobilization of both pouches. Gastroplasty had a limited field in the treatment of hour-glass contractions due to the fact that it was suitable only for those cases in which the pouches were movable, their walls free from induration, and the contracted area narrow. It was simple, easy to perform, and permitted direct inspection of the interior of the stomach, thus affording an opportunity for treating an active ulcer by excision or cautery application. It might be combined with pyloroplasty or gastroenterostomy if the pylorus was stenosed. Four of the writer's cases were operated on by this method. The end results in this group of cases had been most satisfactory, although in one the hour-glass deformity, to a certain extent, persisted to the present time, three and one-half years after the operation. Gastrogastrostomy was especially adapted to the cases in which the stomach was adherent along the lesser curvature to the liver, in which the pouches were relatively large, nearly equal in size, and could be approximated at their dependent portions. The stomach wall should be free from induration at the site selected for the anastomosis. The pylorus must be patent; otherwise pyloroplasty or gastroenterostomy would have to be added. Gastrogastrostomy was performed in three of the cases in this series with complete clinical recovery in each instance, one of the patients having been followed for nine years. Medio-gastric resection or resection of continuity was the ideal operation for hour-glass deformity of the stomach provided the pylorus was not stenosed, and should be performed in all suitable cases. The ulcerated area, active or quiescent, as well as the constricted portion of the stomach wall, was removed by this method. The end results demonstrated the value of this method but unfortunately it was limited to the cases with few adhesions in which the pouches were fairly large and permitted of free mobilization. It was a longer and more difficult operation to perform than those already mentioned, and for this reason, if the patient was in poor condition, should not be given preference over them. In order to overcome the tendency for the constriction to persist after resection in continuity, a wide excision should be made. Mid-gastric resection was the method adopted in five cases. In three a perfect result seemed to have been obtained. In a fourth case there was a persistence of the deformity and the patient continued to have some distress in her stomach. The fifth case died of pneumonia on the sixth day after operation. The 15 surviving patients had been examined and checked by radiographs during the past few weeks. All had gained in weight and, with the one exception noted, were practically free from the symptoms for which they sought relief. Some of each group had been followed sufficiently long to warrant the claim that a cure had been effected. From a study of the clinical results, the writer felt justified in concluding that each of the four operative procedures above mentioned gave equally good results provided the correct one was applied in a given case, and was executed in a proper manner.

Conservative Surgery of Chronic Intestinal Stasis.—Dr. Frank C. Yeomans presented this communication: After reviewing the factors responsible for intestinal toxemia, the essayist said that, stimulated by the work and writing of Mr. Lane, the entire subject of chronic intestinal stasis and toxemia had been restudied from every angle, in recent years. As a result some internists held (erroneously) that all cases were purely medical, while the surgeons had been either conservative or radical, with the recent trend toward conservatism. Was there a surgery of chronic intestinal stasis and, if so, what were its indications? The answer was in the affirmative (with limitations) and the sole clear indication was intestinal obstruction, either mechanical or physiological. This occluded organic stricture but included all lesions that interfered with normal physiology. The speaker then reviewed the lesions amenable to conservative surgery and commented on the more radical measures. Of the former lesions he spoke of anal fissure or irritable rectal ulcer with hypertrophied, spasmodic sphincter muscle which became obstructive and was relieved by simple incision of the muscle under local anesthesia. Houston's valves when thickened and obstructive were divided by a spring clip applied in the office. The sigmoid colon was a point of segmental delay often neglected. When it was free, oil enemata would restore normal physiology in most of the simple cases. Bands and adhesions that held it fixed and kinked must be divided. Recurrent volvulus required sigmoidopexy or shortening of the mesosigmoid. Nothing but removal of the involved segment of bowel would cure true cases of Hirschsprung's disease. The speaker reported several cases illustrative of conservative surgery of the sigmoid. Spastic constipation was to be differentiated from stricture by *x*-ray plates taken at different times. Surgery was indicated only when a diseased appendix, prolapsed kidney, or other lesion was found that was responsible for this reflex disturbance. In general enteroptosis or Glenard's disease, distortion of the intestines, as shown by the *x*-ray configuration, was not of vital import provided the organs had adjusted themselves to their new relations and were functionating in harmony. Surgery, however, might be required for particular segments as the prolapsed stomach or the transverse colon prolapsed into the pelvis, especially if adherent were there. The so-called hammock operation of Coffee had been very beneficial in the latter. Peritoneal bands and omental adhesions were met in most unexpected places and their division yielded excellent results. Deformity of the long prolapsed cecum and ascending colon and their constriction by bands, adhesions and "veils" gave less favorable surgical results. To sum the whole question up from an operative standpoint the surgeon must approach the open abdomen with an open mind, prepared to do whatever could safely and conservatively be done to relieve the pathology discovered. Surgery alone would effect a cure in cases in which obstructive or mechanical factors amenable to operative relief were responsible for the stasis. In other cases, however, in which profound tissue changes and marked general toxemia were present, operation was only the first step in treatment. The physician must keep these cases under observation and direct their hygiene, diet, and mode of life with the object of relieving the toxemia that had been years in developing, otherwise the patient would not derive the full benefit of his operation and even conservative surgery when properly performed in carefully suspected cases, would be discredited.

Dr. John D. Stewart expressed his thanks to Dr. Yeoman for offering him the privilege of discussing his excellent paper. It was said on reliable information that from 75 to 80 per cent. of constipation was rectal in origin, that was, the predisposing factor was found within one to three inches from the anal margin. The most common were the various forms of proctitis which gave rise to the hypertrophic changes seen in

the thickening of the anal papillæ, external and internal sphincter, Houston's valves, and the most noticeably inflammatory changes found in the levatorani muscle. Frequently in examining these cases one would find this muscle so enormously thickened and enlarged that it had much the feeling of a rope, supporting the rectum posteriorly. Invagination of the sigmoid was frequently observed as a causative factor in constipation. Frequently patients would say when they had to go to stool that at first the bowel would move easily and the movement would be sufficient in amount. Then there was a sensation that something remained and after straining they forced the invaginated bowel down into the rectum. A large number of cases of constipation or obstipation (the more appropriate term)—in which abdominal conditions were present, particularly where the lumen of the gut was obstructed by external conditions, as adhesions of the appendix or gallbladder, diseased adnexa, etc., causing angulations, kinks, and adhesive conditions—as Dr. Yeoman so well put it, should be dealt with surgically. Sigmoidopexy in cases of true invagination, those in which all the coats of the bowel were involved, most frequently were attended by very excellent results. Dr. Yeoman spoke of the efficacious manner in which many rectal conditions might be relieved under local anesthesia. This was quite true, particularly in fissures, which were the most painful rectal disorders with which we came into contact and the easiest to relieve, and with which constipation was so frequently associated. To be very frank, these cases of intestinal stasis, aside from ileocecal insufficiency and ptosis, were evidence of a condition that could only be dealt with surgically.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, October 24, 1917.

Dr. Moses Behrend, Vice-President, in the Chair.

Some Unusual and for the Most Part Unrecognized Forms of Ringworm.—Dr. M. B. Hartzell observed that while all are familiar with the ordinary forms of ringworm, represented by scaly annular patches on non-hairy parts and by round, partly bald areas covered with stumps of hair on the scalp, both of which are common in children, but few are acquainted with the varieties seen for the most part in adults and which resemble in some instances eczema of the hands and feet. These forms, known as eczematous ringworm, approach both in their clinical and histological features the infectious granulomata. Dr. Hartzell's reference was principally to the unusual and generally unrecognized forms, showing on the screen examples of exceptionally severe and extensive ringworm of the axillæ and thighs, eczematoid ringworm of the hands and feet and deep ringworm of various regions presenting severe and extensive follicular inflammation in a few instances accompanied by ulceration. Some twenty lantern slides were exhibited showing the clinical and histological features of these unusual varieties of ringworm.

Interpretation of the Causes of Salvarsan Reactions Based Upon Laboratory Studies.—Dr. Jay F. Schamberg read this paper, which was illustrated by lantern slides. He said it had been definitely established that dioxydiamino-arsenobenzol dichlorhydrate (salvarsan) was the most remarkable synthetic chemical compound introduced into medicine and the premier remedy in syphilis and certain other affections. An exhaustive study of the toxicity of the drug undertaken with his colleagues, Drs. John A. Kolmer and George W. Raiziss, had justified the following conclusions: (1) Salvarsan may be used in concentrated solutions up to 0.6 gms. in 10 cc. *in animals;* without any increase in toxicity. (2) The failure to neutralize the solutions of salvarsan with alkali leads to an increase in toxicity of fifty to sixty per cent. in solutions of ½ to 1 per cent. concentration. (3) The addition of a moderate excess of alkali beyond the amount required for neutralization does not increase the toxicity, though untoward effects are possible. (4) The use of sterile, freshly distilled water appears to possess advantages over sterile, stale-distilled or non-distilled water with regard to toxicity, although this difference is not pronounced. (5) Salvarsan in alkaline solution tends to undergo oxidation on standing, with consequent increased toxicity. The rapidity of oxidation and degree of toxicity, however, are variable. If a delay of two or three hours after preparation is unavoidable in its use the solution should be kept in a cylinder full to the stopper that no air may be present. (6) Immediate, early, and delayed reactive symptoms may occur after the use of salvarsan. The "immediate" symptoms are due to a paresis of the blood vessels; the "early" symptoms coming on in a few hours are febrile and gastrointestinal in character, and the "delayed" may be referable to the brain or the liver and gastrointestinal tract. (7) The etiologic factors in the reactive phenomena may be related to the patient, the technique, and to the medicament. We believe that the most important factor is referable to the drug. It is our belief that the immediate vasoparetic reactive symptoms are due to traces of an unidentified impurity in the drug, which we have for convenience termed *substance X*, and that they are not due to 'arsenoxide.' (9) Salvarsan and its congeners are not compounds of absolute chemical purity. We cannot, therefore, expect absolute constancy in biological effects. (10) Salvarsan and its congeners may vary, within certain limits, in therapeutic effect, and to a greater degree in toxicity. The ampoules obtainable in the open market exhibit striking variations in toxicity. (11) Even the poorest compounds are tolerated by animals in much higher amounts than the maximum dose administered to man. There is, therefore, nearly always a latitude of safety. (12) We believe that the commercial products should be tested out intravenously as well as subcutaneously, and that they should be tolerated by rabbits in the dose of 60 mg. per kilo of body weight. (13) Salvarsan is a safer substance than mercury and can be tolerated intravenously by white rats in fifty times the dose of the latter, weight for weight."

X-Ray Treatment of Diseases of the Skin.—Dr. George E. Pfahler employed the *x*-ray in diseases of the skin for (1) the stimulating effect, as in eczema; although comparatively few eczemas should be subjected to this treatment; (2) for the destructive effect, as in epithelioma; (3) for the production of atrophy, as in the treatment of keloids. Many obstinate chronic inflammatory lesions would yield to the stimulating effect of *x*-ray treatment. He estimated that from 85 to 90 per cent. of the basal-cell epitheliomata would yield to treatment by the *x*-ray and that all of such type of epithelioma should yield to the combination of electrocoagulation and *x*-ray. In squamous cell epitheliomata which were more difficult to treat he believes the best results are obtained by the combination of electrocoagulation and the *x*-ray. This he said was particularly true of lesions of the mucous membrane of the mouth. The reduction of keloids was possible by application of the *x*-ray continued over a long period. When practicable good results were possible by careful excision of the keloid followed by immediate application of the *x*-ray to a sufficient degree to prevent recurrence.

Dr. Albert Strickler agreed with Dr. Hartzell that the forms of ringworm described were far more frequent than suspected. Examination for the ringworm fungus was so easily made that he feels that a further spread of the knowledge of the cases of real ringworm by this means would add greatly to the possibility of cure. In connection with the reactions of salvarsan he cited an incident in a case of syphilis which Dr. Schamberg had asked him to attend during his absence. Although the same preparation employed by Dr. Schamberg had been used by Dr. Strickler the man became very sick on the table. A few days later the patient reported that his illness was due to his lack of faith in the ability of the doctor to give the treatment. The case illustrated, Dr. Strickler thought, the individual idiosyncrasy in the matter of salvarsan. Dr. Pfahler's statement that acne and eczema should not always be treated by the *x*-ray was gratifying to Dr. Strickler, believing as he did that many cases of eczema were due to food; some to nerves. Such cases he said were not often benefited by the *x*-ray and after continued treatment by this means, cure by any means was most difficult. A case in point was cited of a young girl under his care at the present time who for two years had been treated with the *x*-ray for eczema of the face and arms. A study of the case had shown food to be the etiological factor.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Virginia State Medical Examining Board.

June, 1917.

ANATOMY.

1. Ulna—(*a*) Description of articular surfaces. (*b*) Relations to other bones. (*c*) Action.
2. Patella—(*a*) Shape. (*b*) Size. (*c*) Location. (*d*) Function.
3. Diaphragm—(*a*) Location. (*b*) Relations. (*c*) Openings.
4. Femoral Artery—(*a*) Course. (*b*) Relations.
5. Ulnar Nerve—(*a*) Origin. (*b*) Course. (*c*) Distribution.
6. Pancreas—(*a*) Location. (*b*) Relations. (*c*) Description of duct.
7. Hernias—(*a*) Usual locations. (*b*) Anatomy of Direct Inguinal.
8. Essential anatomy of Spinal Puncture.
9. Essential anatomy of Aspiration of Bladder.

HISTOLOGY.

Histology of the Ovary or Histology of the Testicle.

PHYSIOLOGY AND CHEMISTRY.

1. Define digestion. (*a*) Name the different organs that directly contribute thereto. (*b*) What class of foods are digested in the stomach?
2. What is meant by blood pressure and state causes that influence it?
3. Where is the center of respiration located and how may same be stimulated directly and indirectly?
4. What is the function of serous fluids?
5. Give mechanism of secretion of bile and the function of same.
6. What effect would division of the pneumogastric nerve in the neck have on the heart's action; and secondly, galvanization of the peripheral ends?
7. Earthy phosphates being insoluble in water, why are they held in solution in normal urine? (*a*) What abnormality precipitates them?
8. Give source and manner of obtaining iodine. (*a*) Give test for detecting same.
9. How do you estimate the amount of carbon and hydrogen in organic compounds?
10. What tests may be used in detecting the presence of morphine, brucine, and strychnine?

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

1. Define serum therapy and name those that have proven most valuable.
2. Define hypnotics, analgesics, and nervous sedatives and give examples in each class.
3. Compare the therapeutic uses of pepsin and pancreatin, how are they prepared, and in what medium does each act best?
4. Write a prescription for a collyrium, a suppository, and for acute dysentery.
5. In what pathological conditions are diuretics indicated? Give name and doses of four most efficient.
6. Give causes of high blood pressure and state what measures and drugs are indicated.
7. Name the antidote for practically all alkaloids and explain its action.
8. Give the maximum dose of the following drugs and in case of poisoning name chemical and physiological antidote for each: morphine, strychnine, carbolic acid, bichloride of mercury, arsenic.
9. Give causes, symptoms, and treatment of chronic lead poisoning.
10. Give cause, symptoms, and treatment of ptomaine poisoning.

ANSWERS.

ANATOMY.

1. The *upper extremity of the ulna* is large and irregular and presents the olecranon process, the apex of which is received into the olecranon fossa of the humerus. The coronoid process projects from the anterior surface and is received (during flexion) into the coronoid fossa of the humerus. The great sigmoid cavity is on the upper surface, and serves for articulation with the trochlear surface of the humerus; the lesser sigmoid cavity on the outer surface articulates with the head of the radius. The *lower extremity of the ulna* is small and cylindrical, and presents the head, which articulates below with the triangular fibrocartilage, and externally with the lower end of the radius. Above it is related to the humerus, and on the outer side to the radius. Its action is to bring about flexion and extension of the forearm; it also assumes a passive rôle in pronation and supination of the forearm.

2. The patella is a flat, roughly triangular bone, situated in front of the knee joint. It is about four centimeters long and about the same in width. It serves to protect the anterior part of the knee joint, and also increases the leverage of the quadriceps extensor muscle by making it act at a greater angle.

3. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad elliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebræ. Its *openings* are: (1) The aortic, transmitting the aorta, vena azygos major, and the thoracic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor. *Structures in relation with the diaphragm. Above:* Pleuræ and lungs, pericardium and heart; *below:* peritoneum, liver, stomach, spleen, pancreas, suprarenal bodies and kidneys.

4. The *femoral artery* is the continuation of the external iliac, beginning behind Poupart's ligament, passing down the front and inner side of the thigh, and terminating at the opening in the adductor magnus, where it becomes the popliteal artery. It passes through Scarpa's triangle. It is indicated by a line drawn from the central point of a line joining the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur. *Relations. In front:* Skin, fascia, internal cutaneous nerve, sartorius, aponeurotic covering of Hunter's canal; *behind:* Psoas, pectineus, capsule of hip joint, profunda artery; *outer side:* Anterior crural nerve, vastus internus; *inner side:* Femoral vein, and adductors.

5. The *ulnar nerve* takes its origin in the inner cord of the brachial plexus. It passes down the inner side of the axillary and brachial arteries to the middle of the arm. From this point it runs obliquely across the internal head of the triceps, pierces the internal muscular septum and descends to the groove between the olecranon and the internal condyle. It then passes into the forearm between the two heads of the flexor carpi-ulnaris, and descends along ulnar side of forearm, and internal to the ulnar artery, as far as the pisiform bone. It is distributed to the elbow and wrist joints; to the flexor carpi ulnaris and the inner half of the flexor profundis digitorum; to the skin of the ulnar half of the back of the hand, and to the skin of the little finger and adjoining half of the ring finger on the palm of the hand.

6. The *pancreas* lies transversely across the posterior abdominal wall, the large vessels intervening between it and the wall—being on a level with the second lumbar vertebra (and sometimes with the first or third)—lying in the epigastric and left hypochondriac regions—having the stomach in front, duodenum to the right, and spleen to the left—and the aorta, vena cava, celiac plexus, thoracic duct, and diaphragmatic crura behind. It lies behind the posterior wall of the lesser omental cavity and is between the laminæ of the mesocolon of the transverse colon. The head of the pancreas is surrounded by the loop of the duodenum. The tail of the pancreas is in contact with the interno-inferior aspect of the spleen. Peritoneum covers the pancreas except upon its posterior surface. The viscus is about 6 inches in length, 1¼ to 1½ inches in width, and

about ½ inch in thickness.—(Bickham's *Operative Surgery.*) Its canal is the duct of Wirsung, which extends transversely from left to right and opens into the duodenum in common with the ductus communis choledochus.

7. HERNIAS. *Usual locations:* In the inguinal, femoral, umbilical, and ventral regions. *Anatomy of direct inguinal hernia:* The hernia does not occupy the inguinal canal, but leaves the abdomen to the inner side of the deep epigastric artery, through the space known as Hesselbach's triangle. There are two forms of this variety: (*a*) the hernia may escape between the epigastric artery and the obliterated hypogastric artery; (*b*) or it may escape between the obliterated hypogastric artery and the outer edge of the rectus muscle.

8. *Anatomy of spinal puncture.* The puncture may be made in any intervertebral space below the second lumbar vertebra; the space generally chosen is that between the third and fourth lumbar vertebræ. A line drawn connecting the highest points of the iliac crests passes through the spine of the fourth lumbar vertebra. The puncture is to be made in the first interspace above this line, and a little to one side of the median line. The reason is to avoid injury to the spinal cord, which terminates at the level of the lower border of the first lumbar vertebra. In the child, the spinal cord terminates opposite the body of the third lumbar vertebra; hence in children the puncture should be made below the fourth lumbar vertebra.

9. *Anatomy of respiration of the bladder.* The bladder occupies the anterior part of the pelvic cavity, lying behind the symphysis pubis. When empty it is triangular in form; when moderately distended, it is of a rounded form; and when fully distended it is of an ovoid shape, and extends into the hypogastric (or even to the umbilical) region. As the bladder rises into the abdomen it carries with it the peritoneum of the anterior abdominal wall, so that there is an area on the bladder, extending for from one to two inches above the pubes, which is uncovered by peritoneum; through this area a puncture or incision may be made into the bladder without opening the peritoneal cavity.

HISTOLOGY.

Histology of the testicle: "Each testicle is invested by a covering of the peritoneum, the tunica vaginalis, which is reflected from the scrotum. Inside this is a thick fibrous tissue, the tunica albuginea, which sends in processes which effect an imperfect division of the organ into lobules. The processes converge towards a thickening of the capsule at the back of the organ, the mediastinum testis. The ducts of the gland also converge towards this point, and from it there emerges a convoluted tube, the epididymis, which lies along the side of the testicle and passes at its lower end into a thick-walled tube, the vas deferens. The substance of the testis is made up of seminiferous tubules, whose lining cells elaborate the spermatozoa. These tubules begin near the tunica albuginea, run a convoluted course towards the mediastinum, and join with others to open into a straight tubule. The straight tubules join to form a network, the rete testis, and from the rete there open convoluted efferent tubules, which join the epididymis. The seminiferous tubules are surrounded by layers of fibro-elastic tissue with flattened cells. On a basement membrane are found cubical cells, spermatogonia. Between these cells are others placed at intervals. These are tall cells, the foot cells of Sertoli. Next to the lining cells is a layer of larger cells, many of which show mitotic figures. These are spermatocytes. In many tubules there are cells internal to the spermatogonia. These are the spermatids, small cells either rounded or elongated. Transitions between these cells and spermatozoa are also seen. The spermatozoa are seen lying in bundles with their heads in contact with one of the Sertoli cells, and their tails free towards the lumen of the tube."—(*Aids to Histology.*)

PHYSIOLOGY AND CHEMISTRY.

1. *Digestion* is the process by which the food is introduced into the body and prepared in such a way that it becomes suitable for absorption. The *organs concerned in digestion* are the mouth, esophagus, stomach, small intestine, salivary glands, liver, and pancreas. Proteins are digested in the stomach; a slight action also occurs on fats, and milk is curdled.

2. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls. Blood pressure:

MAY BE RAISED.	MAY BE LOWERED.
1. By the heart beating more quickly.	1. By the heart beating more slowly.
2. By the heart beating more powerfully.	2. By the heart beating more feebly.
3. By contraction of the arterioles.	3. By dilatation of the arterioles.
4. By increase in total quantity of blood.	4. By deficient supply of blood to the left ventricle.

3. The respiratory center is situated in the medulla oblongata, on both sides of the posterior aspect of the apex of the calamus scriptorius. The respiratory center is probably automatic; but its activity is excited by: irritation of cutaneous or pulmonary sensory nerves, by the accumulation of carbon dioxide in the blood, by the diminution of oxygen, or by the presence of heat.

4. The *function of serous fluids* is to lubricate the serous membranes and thus allow the gliding of opposed surfaces over each other with a minimum of friction.

5. "The *secretion of bile* is a continuous process, and in periods when digestion is not taking place bile accumulates in the gall-bladder. About the third hour after a meal is taken the gall-bladder is emptied into the lumen of the duodenum, but the mechanism by which the contents are expelled has not yet been ascertained. Bile continues to flow into the intestine during the digestive process, and, later, again accumulates in the gall-bladder. . . . So far as is known, the secretion of bile is independent of nervous action, and is excited by the reabsorbed salts and by secretin."—(From Bainbridge and Menzies' *Essentials of Physiology.*)

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

6. Division of the pneumogastric nerve in the neck will cause the heart to beat more rapidly. Galvanization of the peripheral end, if gentle, will again inhibit the heart and cause it to beat slower; if more strongly, the heart will be slowed or even stopped.

7. The earthy phosphates are held in solution by the normal acidity of the urine; when the urine becomes alkaline these phosphates are precipitated.

8. *Iodine* is not found free in nature; but it occurs in combination with sodium, potassium, calcium, and magnesium in sea water, marine animals, seaweed, and mineral waters. Iodine is *prepared* by heating potassium iodide with manganese dioxide and strong sulphuric acid:

$$2KI + MnO_2 + 3H_2SO_4 = 2KHSO_4 + MnSO_4 + 2H_2O + I_2$$

Iodine is *detected* by the blue color which is produced when it comes in contact with starch.

9. *To estimate the amount of carbon and hydrogen in organic compounds:* "The determination of both elements is made in one operation, by taking advantage of the fact that when a compound containing carbon and hydrogen is heated with cupric oxide all the carbon is converted into CO_2, and all the hydrogen into H_2O. Thus, if $C_2H_6O + 6CuO = 2CO_2 + 3H_2O + 6Cu$. 46 parts of alcohol will produce 88 parts of carbon dioxide and 54 parts of water. The apparatus required consists of a tube of difficultly fusible glass, called a com

bustion tube, about 60 centimeters long, drawn out to a point and closed at one end, a "combustion furnace," in which this tube may be heated, and the absorbing apparatus referred to below. A weighed quantity of the substance of which a "combustion" is to be made (sealed in a small glass bulb if liquid) is placed in the closed end of the combustion tube, along with the requisite quantity of recently ignited cupric oxide, leaving space for the passage of the gases produced. The tube is then placed in the furnace and its open end connected with a U tube filled with fused $CaCl_2$, or with fragments of pumice moistened with concentrated H_2SO_4, whose weight has been determined, and whose purpose it is to absorb the H_2O produced. This first U tube is connected with a "Liebig's bulb" containing a strong solution of KHO, and this in turn with another U tube in all respects similar to the first, both the Liebig bulb and the last U tube having been previously weighed. The purpose of the Liebig bulb is to absorb the CO_2 produced, that of the second U tube to retain water carried over from the Liebig bulb by the current of gas. The combustion tube is then carefully heated until the evolution of gases ceases, when the closed, drawn-out end of the tube is broken and connected with a gasometer containing pure, dry oxygen, a current of which is passed slowly through the apparatus to bring the last portions of the products of combustion into the absorbing apparatus. Finally the U tubes and the KHO bulb are again weighed. The increase in weight of the first U tube is the weight of H_2O produced, every 9 parts of which represent 1 part of H. The increase in weight of the Liebig bulb and the second U tube is the weight of CO_2 produced, every 44 parts of which represent 12 parts of C."—(Witthaus' *Manual of Chemistry.*)

10. *Test for morphine:* A solution of molybdic acid in sulphuric acid (Fröhde's reagent) gives with morphine a violet color, changing to blue, dirty green, and faint pink.

Test for brucine: Concentrated nitric acid colors it bright red, which soon changes to yellow; colorless NH_4HS changes the red to violet.

Test for strychnine: Strychnine forms a colorless solution with concentrated H_2SO_4. If a crystal of potassium dichromate is drawn through this solution, it is followed by a track of color which is first (for an instant) blue, then violet, then rose-colored, and finally yellow.

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

1. *"Serum-therapy proper* is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are."—(Potter's *Materia Medica.*)

Those that have proved most valuable are the diphtheria antitoxin and the antitetanic serum.

2. *Hypnotics* are agents which are used to induce sleep somewhat resembling natural sleep; as chloral, sulphonal, trional.

Analgesics are agents which relieve pain by blunting sensation; as opium.

Nervous sedatives are agents which exert a soothing influence on the system by lessening functional activity, depressing motility, and diminishing pain; as potassium bromide, gelsemium.

3. *Pepsin* is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy. *Pancreatin* is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

Pepsin acts in an acid medium; *pancreatin* in an alkaline one.

Pepsin is made from the glandular layer of the fresh stomach of the hog; *pancreatin* is made from the fresh pancreas of the hog.

4. *A collyrium:*

℞.

Acidi borici, gr. vj.
Aquæ camphoræ.
Aquæ destillatæ āā, ℥j. M.

Sig.—Use as an eyewash.

A suppository:

℞.

Iodoformi, ℥j.
Balsami peruviani, ℥ij.
Magnesii oxidi, ℥j.
Cetacei, ℥ss.
Olei theobromatis q. s.
Misce; et fiant suppositoria, No. xij.

Sig.—Insert one morning and evening.

For acute dysentery:

℞.

Acidi sulphurici diluti, ℥ss.
Tincturæ opii deodorati, ℥j.
Spiritus camphoræ, ℥j.
Tincturæ capsici, ℥ss.
Spiritus chloroformi, ℥ss.
Spiritus vini gallici, ℥jss. M.

Sig.—One teaspoonful, diluted, every three hours.

5. *Diuretics are used:* To dilute the urine, to increase the flow of the urine, to remove liquids from the body (as in dropsy), to remove toxic substances from the body, and to stimulate atonic kidneys.

Example: Digitalis, dose 1 dram of the infusion; water; potassium acetate, dose 15 grains; spirit of nitrous ether, dose 30 minims.

6. *High blood pressure* is observed in arteriosclerosis, chronic nephritis, angina pectoris, cardiac hypertrophy, increased intracranial pressure, lead poisoning, gout.

Remedies are: Cardiac depressants (such as aconite, veratrum viride); drugs which dilate the arteries (such as sodium nitrite, amyl nitrite, nitroglycerin, spirit of nitrous ether, chloral hydrate), and measures which decrease the volume of the blood (such as venesection, cupping, application of leeches).

7. *Antidote for practically all the alkaloids* is tannin. The reason is, that tannic acid forms insoluble compounds with most of the alkaloids.

8. MORPHINE: *maximum dose,* half a grain; *antidote,* strychnine, and solution of potassium permanganate.

STRYCHNINE: *maximum dose,* 1/20 grain; *antidote,* chloral hydrate.

CARBOLIC ACID: *maximum dose,* 1½ grains; *antidote,* solution of sodium sulphate, and dilute alcohol.

BICHLORIDE OF MERCURY: *maximum dose,* 1/10 grain; *antidote,* white of egg or milk.

ARSENIC: *maximum dose,* 1/15 grain of the trioxide; *antidote,* freshly prepared solution of ferric hydroxide.

9. CHRONIC LEAD POISONING. *Causes:* "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

The *symptoms* are: Wrist drop, severe colic around the umbilicus, constipation, feces clay colored, blue line on the gums at the junction with the teeth.

The *treatment* is first to remove the cause; then administer a purge of jalap and calomel combined with opium; iodide of potassium should also be given to help in the elimination of the lead.

10. PTOMAINE POISONING. *Causes:* The ingestion of meat, sausages, fish, milk, oysters, cheese, etc., containing ptomaines.

Symptoms: Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and occasionally cutaneous eruptions.

Treatment consists in the use of emetics and cathartics, or lavage and rectal irrigation. Morphine may be indicated for the relief of pain, and collapse is to be combated by atropine, strychnine, nitroglycerin, external heat, whiskey, etc. After thorough purging, salol, naphthol, or bismuth may be given.

(*To be continued.*)

THE TREATMENT OF HYPOPLASTIC AND MENTALLY IMPAIRED CHILDREN.*

BY E. BOSWORTH McCREADY, M.D.,

WILDWOOD, PA.

DIRECTOR, WILDWOOD HALL; PÆDOLOGIST, JUVENILE COURT OF ALLEGHENY COUNTY; PSYCHOPATHIST, DESERTION AND NON-SUPPORT COURT OF ALLEGHENY COUNTY; PÆDOLOGIST, SOUTH-SIDE HOSPITAL; PÆDOLOGIST, GUSKY ORPHANAGE AND HOME.

IN spite of the fact that mental impairment in children is practically always the result of a correlative physical impairment, the training and education of such children remain for the greater part in the hands of laymen. Medical treatment and advice, or what in any other class of cases would be considered medical treatment and advice, is often administered by those whose only claim to medical knowledge is based upon a few lectures upon the psychoses, an interpretative exposition of Freudian philosophy, and a visit to an institution for the feeble-minded.

To many it seems that the physician is logically the one who should direct and supervise the application of the closely interrelated hygienic, educational, and medical measures necessary for the adequate handling of the class of cases referred to above. The busy general practitioner, pediatrist, or neurologist has not the inclination, time, or facilities to give the detailed attention required. Thus it seems necessary to delegate this function to one who confines his attention to this particular field, which seems worthy of a place in the sun as a branch of medical practice, with a distinctive appellation of its own.

The writer some years ago suggested, after conferring with a leading authority on medical terminology, the name "pedology," which was defined as "that branch of pediatrics in which the physical and mental defects of child development are especially studied and treated by the physician."

The defects with which the pedologist deals are the result of interference, from many and diverse causes, with the normal processes of growth, which causes are either hereditary or environmental in character. Either class of causes may predominate as an etiological factor in a given condition, or group of conditions, to which an individual is subject—seldom, however, is either of these classes found alone.

*Read by invitation before the Clinical Society of the New York Polyclinic Medical School and Hospital, October 1, 1917.

HYPOPLASIA OR DEGENERATION.

(Schema drawn by Dr. Charles P. Noble.)

(*a*)	Hereditary Hypoplasia		Due to defect in the chromosomes, (the chromatin or hereditary material) of the ovum or the spermatozoon of parents.
(*b*)	Environmental Hypoplasia	1.	Due to toxemia in the parent or parents affecting (by poisoning) the ovum, or the spermatozoon, or both—giving rise to a defective (poisoned) impregnated ovum or germ. Preconceptional environmental hypoplasia or arrest.
		2.	Due to toxemia in the mother, or to local disease in the endometrium, leading to poisoning of the germ, the embryo, or the fetus, or to insufficient nutrition of the developing ovum. Antenatal, intrauterine hypoplasia.
		3.	Due to bad environment in postnatal life leading to disease, or to malnutrition, with toxemia, and arrest of development. Postnatal hypoplasia.
(*c*)	Mixed, Hereditary and Environmental Hypoplasia		Due to toxemia in the parent or parents, themselves examples of hereditary hypoplasia, before conception; or to toxemia, or to uterine disease, in the mother during pregnancy; or to bad environment leading to disease in postnatal life, in children of parents having hereditary hypoplasia.

"Hereditary hypoplasia was formerly spoken of as the hereditary diathesis or dyscrasias, as gout, diabetes, tuberculous tendency, the nervous diathesis, embracing hereditary neuroses and psychoses, and including epilepsy. It also embraces the hereditary tendencies due to defects or to reversion of the 'born criminals' of Lombroso, and the 'moral or sexual degenerates' of Krafft-Ebing. With exceptions, those suffering from hereditary hypoplasia are either continuously hyperenergized or are alternately hyperenergized and lethargic—or in the *Wanderlust* group.

"Environmental hypoplasia may be general, or specific as to organs or systems of organs, or diathetic in type. Environmental hypoplasia is invariably associated with a lessened capacity to develop energy. The entire group suffering from environmental arrest are subenergized."

This schema shows the mode of action of the above named causes. Much disagreement exists regarding the relative effects of heredity and environment, chiefly because of the confusion regarding the limitations of each. Many influences commonly considered hereditary are, in reality, purely environ-

mental; as in Class 1 and 2, under B, in the schema. Interference with the natural forces of growth by any vitiating influence interfering with cell development becomes aggravated through the interrelation and interdependence of the various systems of body cells, among the most important of which are those initiators and regulators of correlative growth —the sympathetic, autonomic, and ductless glandular systems. Thus conditions having a vitiating influence upon cell development result in growth disturbances in the developing embryo, and as a further interference with growth forces, in the first few weeks of fetal life when the ductless glands begin to appear, the cells of which they are composed also grow imperfectly; and, as they fail to secrete to the extent to which they were destined, further defective development ensues. As a result we have constitutional inferiority, infantilism, hypoplasia, degeneracy—call it what you will—in varying degree. Of these terms I prefer "hypoplasia." Hypoplasia may affect any organ and any structure and to almost any extent. Thus hypoplasia of the nervous system gives us idiocy at one extreme, and the so-called neurotic make-up at the other.

STIGMATA OF DEGENERATION.

1. Abnormalities in size and shape of the head. Softness or bossing of the cranial bones. Marked gaping or premature closure of the fontanelles and sutures. Undue distention or sinking of the fontanelles.

2. Malformations of the ears. Irregularity in size. Undue prominence or flattening. Misshaped helix, antihelix, tragus, antitragus, and lobule. Supernumerary auricles, auricular appendages, or atresia auris.

3. Anomalies of the eyes or lids. Drooping of one or both eyelids. Epicanthus and palpebral fissures. Congenital cataract, coloboma iridis or ididereмia. Microphthalmus or anophthalmus. Strabismus and nystagmus.

4. Malformations of the nose. Saddle-shaped, exceptionally small and broad, or unduly large and prominent. Partial or complete atresia of the posterior nares.

5. Malformations of the face. Undue prominence of the cheek bones with markedly retracted small chin. Clefts of face and lips. V-shaped or high vaulted palate. Enlarged, protruding, and often cracked tongue. Irregularly shaped and implanted teeth, deficiency or excess in their number. Inability to bring jaws closely together, owing to irregularity of dental arches, hence constant dribbling of saliva from half-open mouth.

6. Malformations of long bones. Curvatures of the bones of the upper and lower extremities. Supernumerary fingers and toes or deficiency in their number. Syndactylism or fan-shaped distribution. Disproportion in size of legs and arms. Talipes, spina bifida, and caudal formations.

7. Umbilical hernia; diastasis recti abdominis. Anomalies of the genitalia; epispadias and hypospadias. Malformations of the anus and rectum. (Sheffield.)

The various stigmata of degeneracy, noted in detail above, are somatic manifestations of hypoplasia. It may some day be possible, when our knowledge of endocrinology has become more complete, to trace by means of the stigmata of degeneracy the retardations and exacerbations in function, changes in chemical complexity and even structural abnormalities of individual glands of internal secretion, even back to early intrauterine and early postnatal existence. More even than this is possible as a result of an enlightened knowledge, it may be that the mysterious directive forces of hereditary transmission will be found, not to reside in the essential structure of the chromatin, but in the intricate harmonic constituency of the cells.

The hypoplastic child is distinguishable from his more normally constituted fellows by various anatomical, physiological, and psychic characteristics. The clinical picture most often seen is the underdeveloped, badly nourished child whose unstable nervous system is still further handicapped by the effects of reflex disturbances arising from nasal obstruction, defective vision, or perhaps phimosis. These and similar conditions are a part—not the cause—of the hypoplastic complex. Such children are subject to delayed epiphyseal union, as revealed by the *x*-ray, hypotonicity of ligaments and muscles, postural defects, visceroptosis, and hernia. Incontinence of urine and feces is frequently present. The *signe du sourcil* (deficiency of the eyebrows in the outer third) is often present and is considered by some a sign of thyroid deficiency. Delayed sexual development is common, though sexual precocity may be found. Premature eroticism leading to sexual misdemeanors is frequent in hypoplastic children—especially in emotional, physically inferior girls. In making examinations in juvenile court work I have been struck by the fact that practically without exception all girls charged with sexual offences have enlarged and over-active thyroids, in many even before the development of secondary sexual characteristics. The high-arched palate produced by yielding of the palatine bones owing to their relative poverty in calcium is a fairly constant symptom of hypoplasia, dental malocclusions are likewise common, and variations in bodily temperature and irregularities in pulse rate are frequent. Abnormalities in size and shape of the sella turcica indicating variations in size and function of the pituitary gland are common in hypoplastic children and within certain limits may be considered merely as stigmata of degeneracy. Information of positive value may sometimes be obtained through examination of the blood and through biochemical studies of the urine.

The following is the blood analysis of a hypoplastic boy who gave a positive Abderhalden reaction to sexual and pineal gland tissue:

Absolute Count: Hemoglobin (Sahli), 105; red blood cells, 6,512,000; white blood cells, 8000.

Differential Count: Neutrophiles, 39; lymphocytes: small, 26; medium, 20; large, (?); eosinophiles, 25; basophiles, (?); monocytes, 45; transitionals, 8.

Remarks.—Blood pressure 120. Wassermann, on March 19 and March 30, shows slight inhibition.

Volume	300 c.c.	
Reaction	acid	
Specific gravity (25°C.)	1.0272	
Color	Pale	
Nitrogen, total	3.730	gms.
" urea	3.538	"
Uric acid	.258	"
Creatinine	.081	"
Total Sulphur (as SO_3)	1.333	"
Inorganic " "	.741	"

Magnesium	.060	"
Indican	low	
Albumin	none	
Sugar	none	

The above is the biochemical analysis of the

urine of a child subject to attacks of petit mal. The uric acid and neutral sulphur are high, while the nitrogen is abnormally low.

In the psychic sphere hypoplasia may manifest itself in aprosexia and psychasthenia (the natural correlates to a condition of general adynamia), in hyperemotivity, in susceptibility to neuroses and psychoses and various perverse tendencies (delinquency, sex perversion and inversion, etc.), in isolated depression of function of higher cerebral centers (congenital word-blindness, word-deafness, etc.), and in mental deficiency sufficiently severe and general in scope to constitute feeble-mindedness.

The first requisite in the treatment of mentally impaired children is the same as that in the treatment of hypoplastic children in general, since it is fruitless to attempt to correct the mental impairment without at the same time stimulating and stabilizing the correlative development of all the forces of growth.

Treatment may be divided into prophylactic, hygienic, medical, and educational.

Prophylactic measures should date not only from the earliest moment of conception but should be applied to the parents at a period even earlier than

Fig. 1.—Esthetic dancing in the snow.

this. While not an ardent believer in the theories of the eugenists as popularly exploited at present, I do believe prospective parents should conduct themselves in accordance with the rules of healthful living and so do much toward insuring the healthfulness of their individual germ cells. After conception the responsibility rests upon the mother. Antenatal hygiene is of an importance not generally realized, though upon it depends, to a large extent, the future stability of the race. Insufficient nourishment, either from lack of food or because of metabolic disorders, worry and emotional disturbances, exhaustion, either as a result of overwork or of an over-strenuous pursuit of pleasure, lack of exercise and fresh air, all these are possible sources of hypoplasia in the offspring. An important phase of the prophylaxis of hypoplasia during the gestational period is treatment by glandular substances of ductless glandular insufficiencies of a minor character in the mother. Dr. Sajous presented an interestingly original paper on this subject before this society last year, the discussion upon which it was my honor to open. Trauma during labor is a frequent cause of mental impairment; the prevention depends upon proper obstetrics and the early relief of pressure symptoms as advised and practiced by Dr. Sharpe. Equal in importance to the prenatal period of existence is the period of infancy. Nutritional disorders during the first year are frequent causes of interference with growth forces. When one sees and considers what infants have to contend with, it is a wonder that any of them grow into childhood. Unusual care must be exercised when maternal nursing is not possible, not only because of the dangers incident to artificial feeding but also for the reason that the inability of the mother to nurse her child is frequently due to the fact that she herself is hypoplastic and consequently is unable to transmit to her offspring the vital force necessary to the energization of the processes of normal growth. Such children react intensely to all untoward influences of the environment—hygienic, pathogenic, and disciplinary, and if they survive make up a large number of our adult neurotics.

Treatment of hypoplastic children should be initiated as early as possible. The younger the child the better the chance of counteracting faulty hereditary influences and correcting the effects of improper environment. Among the most important of the hygienic measures is the matter of diet. The diet of the hypoplastic child should be based upon scientific principles. Not only should the caloric value be regulated according to his needs but the proportion of protein, fats and carbohydrates as well.

In the above table the first column gives the amount of each article of food in bulk, the second column the total number of calories contained in that article, the

third column the number of protein calories, the fourth the number of calories in fat, and the last column the number of calories derived from the carbohydrates. At the bottom of each column is shown the total of each for the meal, from which is subtracted the correct ratio, upon a basis of 3/15 protein, 2/15 fat, and 10/15 carbo-

hydrate, leaving an unavoidable variation which should not be greater than ten calories.

Ordinarily children, even of the well-to-do, do not have enough to eat. A child of twelve years, receiving the proper amount of exercise and fresh air, can very easily consume thirty-five hundred calories a day, sufficient to maintain in good health an adult at hard labor. The inordinate craving for sweets manifested by so many children is simply an outcry from starved tissues for more nourishment. The value of fresh air as a hygienic measure cannot be over-estimated. For this as well as for other reasons, hypoplastic children should never be subjected to the close confines of city life. Recent experiments show that it is not from the chemical content of "close" air that ill effects arise but rather through the absence of motion in such air, depriving the peripheral nerve endings of the nor-

Fig. 3.—Sleeping tent.

mal stimulation received from the varying currents present in what we call fresh air. In order to enhance the effect of fresh air clothing should not be impermeable, but should be as light and porous as can be worn without actual discomfort. The body surface soon becomes accustomed to contact with the elements and able to adjust itself to sudden and frequent thermic changes. There is no better way of improving nerve tone and stimulating metabolism and nutrition than this. The "barefoot boy with

Fig. 4.—Open-air sleeping shack.

cheek of tan" has many advantages over his hothouse cousin whom sun, rain, and wind must not come near. Fashion permits her children's knees to go bare, but except in the drawing-room, studio, and upon the stage views bare feet with contempt. Fig. 1 shows a child for whom "cold feet" has no terrors. Exposure of the entire body to sun, wind and rain is another valuable adjunct to treatment. Fig. 2 shows a child receiving a sun-bath in the open in mid-winter. I believe that the ill-effects ascribed to sun-baths are due to sudden and prolonged exposure but mostly to the effect of the glare of the sun upon the eyes. With proper preparation and the use of a black shade this danger is prevented. Open-air sleeping I consider a necessity in the treatment of hypoplastic children. Figs. 3 and 4 show various types of sleeping tents containing four bedroom compartments and a living

Fig. 5.—One-room sleeping shack.

room, and Fig. 5 shows one with but one large room. More delicate children should be inured to outdoor sleeping by degrees. Swimming in outdoor pools is beneficial not only as a hydrotherapeutic agent but also as an opportunity for free, unre-

strained exercise. Walking has become in this country since the advent of the automobile almost a lost art, though there is no more healthful form of exercise, especially cross-country hiking in hilly regions. As in other forms of outdoor activity,

Fig. 6.—Tobogganing as a means to repress fear and gain self-reliance.

the benefits are psychic as well as physical, for all tend to develop self-confidence and emotional control and to eradicate that bug-a-boo of the neurotic —fear. This advantage is possessed by both skating and tobogganing to a marked degree. (See Fig. 6.)

I have, after a number of years' experience in the treatment of hypoplastic children, come to rely upon but few drugs. Certain tonics and alteratives have their temporary use, but my chief reliance is upon physical measures, aided by organotheraphy. We are far removed from the crude empiricism of the days of Brown-Séquard and his over-enthusiastic followers. A fund of knowledge is in process of acquisition which places endocrinology upon a rational foundation and furnishes concise indications for the administration of definite gland substances in definite disease conditions. While hypoplastic children very often present symptoms pointing toward dysfunction of individual glands, as the thyroid, pituitary, adrenals, etc., in the majority the implication is pluriglandular.

I have found the following pluriglandular formulæ of great value as aids to the stimulation of meta-

Fig. 7.—Gymnastic exercises.

bolic processes and the forces of growth by bringing into equilibrium the various glands with their common though tangled relationships, with resulting improvement in nerve tone, in mentality, and bodily resistance.

Hydrotherapy, massage and other forms of mechanotherapy are, when indicated, of the greatest value. These measures are particularly useful in the type of spastic cases with which Dr. William Sharpe of New York City has such great success, both in preparation for operation and as an adjunct to postoperative treatment. We have found that in the children who have been subjected for a few months before operation to the hygienic and therapeutic measures outlined above the risk is greatly minimized, the reaction is less, and con-

Fig. 9.—A lesson in articulation.

valescence is shortened. After convalescence the same measures enhance the favorable effects of the operation.

Swedish and other forms of gymnastics may be classed under medical measures, though they have

great hygienic and educational value as well. Esthetic dancing, folk dancing, and eurhythmics are likewise types of activities whose value cannot be exaggerated. It is difficult to draw a sharp line of demarcation between measures which are strictly educational and those which by broad interpretation would be considered medical and hygienic; for education, according to the new Standard dictionary, "includes not only the narrow conception of instruction, to which it was formerly limited, but embraces all forms of human experience, owing to the recognition of the fact that every stimulus with its corresponding reaction has a definite effect upon character." Every act of the child's daily life should be utilized for educational purposes in the systematic development and cultivation of the normal powers of intellect, feeling and conduct. Education is not something which can be administered like medicine out of a spoon, though this seems to be the prevalent idea—so much child, so much education. Formal educational measures are important—no one realizes this better than the writer—but to attempt to impart the three R's to a child, mentally impaired or not mentally impaired, whose

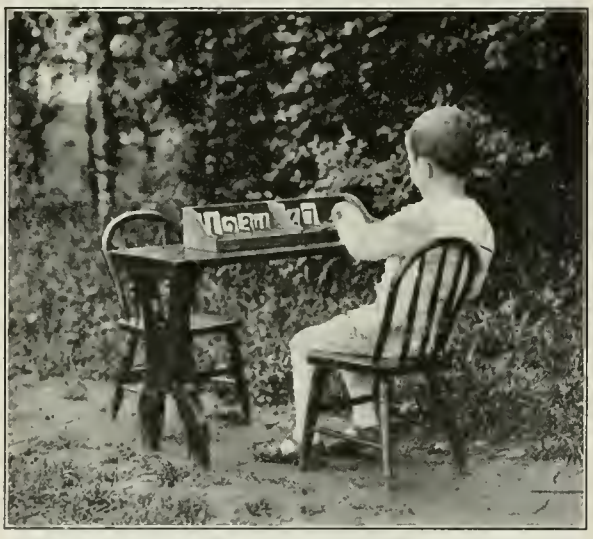

Fig. 10.—Boy working Montessori material.

nervous system is not supplied with good red blood or whose nervous system is incapable of proper coordinate control, is not education. The child's body must be educated as well as his mind, and the former is more important than the latter; to obtain the best results the two must be used synchronously.

The Montessori and kindergarten systems offer much that can be profitably adapted to the education of hypoplastic children. The specific requirements of individual children necessitate that methods shall be adapted to the child, not the child to the methods; consequently no system can be used in its entirety. Defects of speech require special training in articulation and breathing, as do word-blindness, word-deafness and other deficiencies, insufficiencies and irregularities in function of various special organs and faculties. Weather permitting, all instruction should be in the open air. Fig. 9 shows a lesson in articulation. This child, though she hears perfectly, has never talked. Training is more promising of results since Dr. Sharpe performed a decompression operation. Fig. 10 shows a little boy working with some of the Montessori material two weeks after an operation for external hydrocephalus by Dr. Sharpe.

I have in this paper endeavored to show that in the larger proportion of mentally impaired children the impairment is but a symptom of the general hypoplastic condition, that the improvement and cure of such children depends on the stimulation of the correlative forces of growth, and that any line of treatment or education is futile which does not reach and correct the underlying causes.

AN INTERESTING CASE OF BILATERAL URETERAL CALCULUS.*

By LEO BUERGER, M.D.,

NEW YORK.

ALTHOUGH the occurrence of bilateral renal calculi is so frequent as to arouse but little com-

Fig. 1.—Shadowgraph catheter forms a loop in the right ureter, the two shadows being considerably removed. Note grouping of the shadows in the right ureter and their medial position.

ment, the simultaneous occurrence of calculi in the ureters is much more rare, particularly when the calculi are mutiple. A case that has recently come under my observation presented a sufficient number of points of interest to warrant my bringing the matter up before you to-night, all the more so, since a number of instructive points in radiographic and cystoscopic diagnosis could be visually demonstrated in my series of radiograms.

S. F., female, 36 years of age, mother of five children, consulted me on the 28th of July, 1917. She had been operated upon 4 years previously, and a stone is said to have been removed from the right ureter. For

*Read before Surgical Section, New York Academy of Medicine, Oct. 5, 1917.

the past 6 weeks she had been complaining of pain in the left lumbar region, radiating down into the hypogastrium, but this pain had recently disappeared only to give way to a much more severe attack of colic in the right lumbar region, and radiating down into the right iliac fossa. I saw the patient on the 28th of

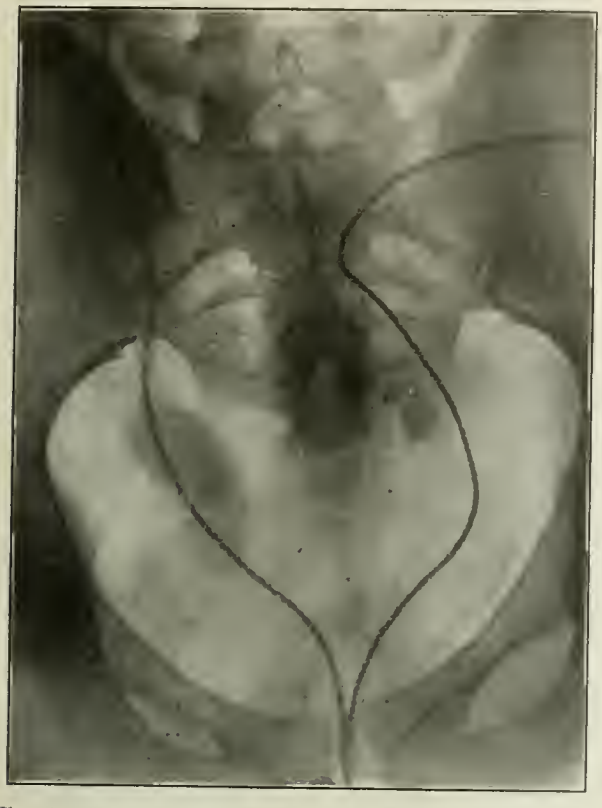

Fig. 2.—Shadowgraph catheter in right ureter passes far into the iliac fossa. Thorium solution in lower left pelvis makes a mass in which the two denser shadows represent calculi in a dilated ureter.

July, when she was in an attack of severe right iliac pain which necessitated an injection of morphine.

A radiographic examination made early in August, 1917, failed to show any definite evidences of calculi in the pelvic region, but some indefinite shadows, not far removed from the left ureter in the pelvis, were faintly visible. A subsequent *x*-ray, however, showed clearly that there were 5 distinct shadows in the pelvic region, presumably in the path of the right ureter, and 2 somewhat larger shadows, possibly in the left ureter, somewhat above the level of the sacro-iliac synchondrosis.

Cystoscopic examination on August 13, 1917, demonstrated the presence of a hydro-pyonephrosis on the right side, although the ureteral catheter met with *no obstruction*, suggestive of the presence of calculi. In the left ureter no obstacle was met, and perfectly clear urine of normal concentration with practically no abnormal element was obtained.

In short, in spite of the evidences suggesting the possibility of 5 calculi in the right ureter, possibly 2 in the left ureter, low down in the pelvis, cystoscopic examination showed no conclusive data other than the presence of purulent urine on the right side. On the left side nothing suspicious of calculus had been demonstrated.

Because of the presence of the clear urine on the left side and the questionable 2 shadows, I determined to pass a shadowgraph catheter in the left ureter. The catheter passed upward 20 cm. or more without encountering any obstruction. What was my surprise, therefore, when the radiographic plates (Fig. 1) showed that the catheter had not ascended the ureter, as I had thought, but had turned back on itself, forming a loop, whose upper end was situated over the sacro-iliac synchondrosis and the sacrum (Fig. 1). Surely this indicated an enormously dilated ureter, and increased the suspicion that the 2 shadows were calculi, even though they were not in direct contact with the shadowgraph catheter.

With a view to determining conclusively whether the 2 shadows in the lower pelvic region were lying in the ureter, and furthermore, with a view to identifying the 5 shadows on the other side, before deciding upon any operative procedure, it was deemed advisable to inject thorium nitrate into the left ureter, and to pass a shadowgraph catheter into the right ureter. Fig. 2 demonstrates the sausage-like mass of thorium in the lower left ureter, in which the 2 shadows suggestive of calculus are seen to lie. This was regarded as conclusive proof of the identity of the 2 shadows. On the right side the catheter is seen to take an unusual course, forming an angle over the sacrum and passing well into the iliac fossa.

The question arose as to whether the ureter had been perforated, but the subsequent course, the lack of untoward symptoms and the condition of the ureter found at operation, proved definitely that no perforation had occurred. Here again (Fig. 2), the 5 shadows were not found to be in contact with the catheter, but had taken a new position, re-arranging themselves over the sacrum, suggesting either mobility in a dilated ureter, or the possibility of their being extra-ureteral. It was decided to take another radiogram (Fig. 3), where another grouping of the shadows on the right side had taken place.

In view of the abnormal course of the shadowgraph catheter, and in view of the regrouping of the shadows, and the fact that they were not directly in contact with the shadowgraph catheter, I decided that we were dealing with a hydro-ureter of considerable size, and determined to do a ureterotomy.

On August 29, 1917, the right ureter was exposed through a Kammerer incision, and found enormously dilated and tortuous, so that it was easily displaceable into the iliac fossa. The 5 stones were palpated, found lying in the situation represented in the radiogram, and easily removed through a longitudinal incision. This

Fig. 3.—Five calculi in the right ureter. Note grouping and mesial situation, two calculi in left ureter.

was closed by 2 layers of fine chromic suture. The patient made an uneventful recovery, was out of bed on the 12th day, and the wound was completely healed after 2 weeks.

The lessons that may be drawn from a study of

the cystoscopic findings and x-ray plates are the following:

1. The existence of multiple calculi, even when they occur in both ureters in the lower pelvic region, may be overlooked if the radiographic plate be not sufficiently clear.

2. The collection of clear urine from one kidney does not exclude the existence of single or multiple calculi, even when such calculi are of considerable size, nor does the absence of any obstacle to the passage of a ureteral catheter exclude the existence of such calculi.

3. The use of a shadowgraph catheter, although demonstrating the path of the ureter when the latter is of normal width or slightly dilated, will fail to indicate the identity of suspected ureteral calculi (ureteral shadows), when the ureter is considerably dilated. Under such circumstances it will fail to coincide with the suspected shadows.

4. A ureteral catheter may form a large loop in the ureter, which can be demonstrated by radiographic plates without giving any sensation of obstruction to the manipulating hand.

5. When a radiogram demonstrates that a shadowgraph catheter has formed a loop in a ureter, suspected calculi and suspected shadows may lie in the ureter, although they be considerably removed from it.

6. Where a shadowgraph catheter takes an unusual course and appears to pass outward beyond the region of the ureter far over into the iliac fossa, it must not necessarily have perforated the ureter, but may be lying in a much dilated and tortuous channel.

7. When a collection of suspected ureteral shadows appears to be arranged in a row in one plate (Fig. 1), and subsequently becomes arranged in a clump, in short, when such shadows have evident motility, they may still be ureteral calculi, for they may lie in a hydro-ureter, which permits of wide range of motion.

8. When suspected ureteral shadows lie far mesial, and seem to overlap, or overlie the lateral portions of the sacrum, a situation too far mesial for the ordinary ureteral course, the shadows may nevertheless be ureteral calculi in a much dilated ureter.

9. Finally, when a suspicious row of shadows in the pelvic region takes a vertical direction, instead of a path with a concavo-convex outline, such as is usually expected in the pelvic portion of the ureter, we may be fairly certain that we are dealing with a hydro-ureter.

1000 Park Avenue.

THE LIBRARY OF THE ARMY MEDICAL MUSEUM.

By R. W. Shufeldt, M.D.,
Washington, D. C.
Major Medical Corps, U. S. Army (Ret.).

Having pointed out the pressing necessity for erecting and equippping the new Army Medical Museum, in that we might be prepared to meet what will very soon be required of that institution in the present war,[1] it is my aim to register, in this article, a similar plea for the library of the museum, considered apart from what was touched upon in my former contribution to the subject.

There is a very obvious difference between a medical museum and a medical library, when each is considered with respect to its usefulness, and either approaches an overstocked condition. As has been shown in my previous article, the museum first uses up all of its available space for the exhibition of the specimens that come steadily in. But the inevitable happens, eventually; no more space is to be had, and, for a greater or less time, overcrowding follows. This in turn results in an inability to accommodate further material or accessions through a sheer congestion of every inch of exhibition shelfage and floor-space. Later on, specimens cease to come in, or only a few per year, while appropriations and donations fall off to a large degree; in a few years more the institution becomes a veritable

Fig. 1.—Title page of the first edition of *De Humani corporis fabrica* by Andreas Vesalius.

antiquity and a fixture. It reminds one of a house in which some great personage has passed away. We see all his ordinary belongings, just as he left them at the time of his death; nothing is ever added, nor is anything, at any time, taken away; a mummified reminder of former days, with the spirit of activity withdrawn.

This is the present condition of the Army Medical Museum. For altogether too many years past it has been practically dead—it has come down to the stage of the watchman and the duster, and a few curious sight-seers pass daily through its silent and antiquated alcoves. In the meantime, England is, I understand, passing us in such achievements by leaps and bounds; and to prove it one has but to

appreciate what is being done at the Royal College of Surgeons of England, in London. But it is not my purpose to go into this matter in the present contribution.

As stated above, the condition and needs of the library of the Army Medical Museum offer a very different proposition, compared with what the Museum suggests. A library will grow where a museum will stagnate, e'en though both be under the same roof, as is the case in the present instance. Fire, alone, can utterly destroy a library; while the abrogation or entire suspension of its supporting income may powerfully curtail its usefulness. When its shelving capacity for books and other publications has been arrived at and passed, proper relief is demanded—if it be only for the credit of civilization and the requirements of a progressive literature and science.

There are many problems offered on the part of the present library to be considered, and, presumably, all these problems will be solved when the new Army Medical Museum is built, and the museum, library, and staff, with its various departments, are moved into it. That is an event which cannot be consummated any too soon. In the meantime, however, books, journals, manuscripts, and much other library material, continue to come steadily in, and it is a serious question as to how to properly manage all such matters under existing conditions, in order to sustain the world-wide usefulness of this professional library of all medical libraries of the world to-day. At one time it was seriously considered to merge this library of the Army Medical Museum—or of the Surgeon General's Office, as it is more generally known—into the Library of Congress; but fortunately such a great mistake—indeed, a calamity of the first magnitude—was escaped.[2]

It may be said in passing that the Medical Department of the army is justly proud of this library, and of the fact that it is under its control. Moreover, the Medical Department is directly responsible for its establishment; it has most successfully managed its affairs and career from its very inception, and, in the name of all that is fair, no change of the kind not long since suggested, should ever remove this time-honored institution from the custodianship of those who now have its welfare in charge.

Without entering upon any details along this line, it may be said, with all truth, that this library has, up to the present time, served the cause of medicine in all of its departments, in the most efficient manner possible, as thousands of physicians and surgeons, from all parts of the world, will be only too glad to testify to and proclaim. The time has come, however,—as it was certain to do sooner or later—when this library has outgrown the quarters, support and assistance that have united to sustain it for so many years. It stands much in need of a more liberal appropriation by Congress, when the usual annual appropriations are made. Its available space for books, journals, and other library material is practically exhausted; there is a crying need for larger rooms, book-stacks, and offices, and, finally, the working staff needs be added to in more than one of its departments.

FIG. 2.—General view of the Library of the Army Medical Museum, showing crowded book stacks.

Be it said to the credit of our civilization, medical literature of all classes is ever on the increase; and, as the library of the Surgeon General's Office aims to have on its shelves a copy of every medical work issued, with a large number of others of allied sciences, as for example those in the several fields of botany, biology, bibliography, biography, and so on, it goes without the saying that a day is sure to arrive, sooner or later, when proper room for more books fails to exist. A year ago last August there were, bound and unbound, 224,522 volumes in this library; adding the pamphlets to these, the total amounted to 561,642. At the time stated, the library was receiving and placing on its shelves, by way of current periodicals, 1865, not including incidental accessions.

In this library there is a large number of absolutely priceless volumes on medicine, some dating back to the very dawn of history; but, up to the present writing there is no adequate means in the library room for exhibiting these treasures as they should be exhibited. Some of these books are kept in glass-covered cases; but the latter are totally inadequate and altogether unsuitable in style. They are of an out-of-date pattern; occupy altogether too much floor-space, and should be relegated to the museum for specimen exhibition. They should be replaced by at least six cases of the style and proportions to be seen in the Library of Congress, and there used for the display of unique volumes. This could easily be afforded for the library as it now stands, and these cases subsequently used for the same purpose in the new Army Medical Museum, when it is finished and the library is duly moved into it.

Congress should make an annual appropriation for this library of no less a sum than $40,000; and it would be an excellent plan to have it opened for the convenience of those entitled to use the works contained in it, several hours on Sundays—that is, from 9.30 a. m. to 4.30 p. m. To make this effective, the staff should be increased to meet the requirements, and should receive salaries coequal with the duties performed At the present time the salaries of the civilians on duty in the museum are ridiculously low, compared with the work they perform and with the responsibilities assumed in some instances; so inadequate, indeed, that, as the author of the present article, I am ashamed to cite examples to substantiate this statement.

Since June, 1916, there have appeared at least two very able brochures on the subject of this library; they are both by its present librarian, Col. Champe Carter McCulloch, of the Medical Corps, U. S. Army. The information they convey has proved to be of the utmost use to librarians throughout the world.[3]

In speaking of the present classification of the books and pamphlets in the library, Colonel McCulloch points out that it "Is far from being complete, perfect, or satisfactory. It is only applicable to collections of bound medical books, and not to arrangements of pamphlets and reprints by subjects, which require a more extensive classification. It simply represents the best available in this library under present conditions of shelf-room. The library now contains some 250,000 bound volumes, and only three additional book stacks have been added by Congressional appropriation since the original stacks were put up in 1887. The collection of medical periodicals in the first story of stacks on the floor of the library hall has more than once been shifted and rearranged in order to secure additional shelf-room for incoming files; but it would be impossible to rearrange the above collection of classified books without additional shelf-room in new stacks or in a new building, nor would it be advisable to attempt this except under these conditions, since the present library force is very small and could not attempt the task without seriously interrupting the large amount of current work in which the library has at present to deal."

Some of the rarest volumes on ancient medicine are to be found in this library. In order to give an idea of some of these, a Vesalian illustration has been selected, and a reproduction of it is here published for the first time. (Fig. 1.) It is the title page of the first edition of *De Humani corporis fabrica*, the work of Andreas Vesalius, which, in 1543, marked the beginning of modern anatomical research.

The library also owns a complete edition of the works of Hippocrates, published in the Greek text by the famous printer of Venice, Aldus (1526). Philippus Pincius printed at Venice in 1497 a folio by Celsus; it is his *De Medicina*, in eight books. These are also to be found among the rarities of the library.

A copy of the *Opera Omnia* of Galen (1490), in two large folio volumes, is also to be found in this grand library, as are, indeed, some of the rarest known works in medicine; it should be the pride of every true American in this country that such an institution is in existence here.

In its usefulness, this library is by no means limited to officers of the Army and to local researchers in medicine; it is open to the profession everywhere. In one of his above-cited pamphlets, Colonel McCulloch remarks: "The physician living at a distance can borrow such works as he wishes to consult (except our very rarest specimens and unbound current journals) by sending an identifiable request for them and paying the postage or expressage each way. These he is allowed to keep for two weeks, or for longer periods, on proper request for extension, if there has been no other application for the books. If an individual is unknown at the library, a small deposit is required to cover possible loss; otherwise, and from old 'customers,' no deposit is required. Every facility is given to visitors at the library to consult the card catalog, and copies of the cards can be obtained by the distant worker on the payment of a nominal fee for the labor of copying them outside of office hours. We endeavor to make these transactions as informal and simple as possible, as we are anxious that physicians everywhere should learn the advantage that the library offers and make use of our rich collections to the fullest extent."

Such a valuable and absolutely indispensable institution as this surely deserves every encouragement that can be extended to it, and the most generous financial support that Congress can mete out to it.

As a matter of fact, the building of the new Army Medical Museum is really what is demanded,

and this should be done at as early a day as possible. It is needed in that we may reap at least some benefit from the bloody and expensive war into which we are now plunged.

3356 EIGHTEENTH STREET.

AN INTRATHORACIC THYROID TUMOR.

REPORT OF A CASE WITH AUTOPSY FINDINGS.

BY HENRY MONROE MOSES, B.S., M.A., M.D.,

BROOKLYN, NEW YORK.

ATTENDING PHYSICIAN KINGS COUNTY HOSPITAL; ASSISTANT ATTENDING PHYSICIAN TO THE NORWEGIAN HOSPITAL AND THE HOSPITAL OF THE HOLY FAMILY.

TUMORS of the thyroid gland occur with so much greater frequency above the thoracic cavity than within it that one feels justified in reporting a case upon which a post-mortem examination has been made. Dr. Frank H. Lahey in the *Boston Medical and Surgical Journal*, March 8, 1917, writes that "there is no disease of the thyroid so often overlooked by the physician or surgeon unfamiliar with thyroid diseases as substernal or intrathoracic goiter. Cysts and adenomata of the thyroid occurring as frank tumors of the neck are so self-evident that they cannot be mistaken. Substernal or intrathoracic goiters, on the other hand, present difficulties in diagnosis apparently in inverse proportion to the degree of prominence of the upper pole of the tumor. These tumors are either adenomata or cysts, originating in the right or left lower pole or isthmus of the thyroid and gradually enlarging downward into the thorax along the path of least resistance."

"Two factors enter into the production of the intrathoracic growth of goiter, (1) the path of least resistance for these growths originating at the lower poles of the gland is downward and into the chest, and (2) the upward and downward motion of the thyroid gland in deglutition is the second important factor."

The prominent symptoms are: (1) a feeling of pressure beneath the sternum on swallowing; (2) the feeling of a mass ascending and descending on swallowing; (3) huskiness of the voice; (4) dyspnea; (5) intermittent attacks of suffocation; (6) broken cardiac compensation. This condition should be suspected in some cases of asthma.

Much has been written recently concerning the functions and abnormalities of this gland, but the greater part of the literature is upon imperfect function and changes in size and composition.

The usual classification of the different enlargements are: (1) parenchymatous, in which the enlargement is general and the follicles contain a gelatinous, colloid material; (2) vascular, in which the enlargement is chiefly due to dilatation of the blood vessels without the formation of glandular tissue; (3) cystic, in which the enlarged gland is occupied by large cysts, the walls of which often undergo calcification.

An enlarged thyroid gland may undergo malignant degeneration.

We occasionally meet with thyroid tissue in addition to the normal gland. Such tissue is known as aberrant, accessory or supernumerary thyroid glands and may appear anywhere from the root of the tongue to the arch of the aorta, causing tumors which vary in size from the smallest nodule to those filling the greater part of the chest cavity on one side. A large tumor may compress the trachea causing dyspnea and collapse of the lung, or, passing beneath the sternum, the tumor may interfere with the return flow of blood to the heart, causing signs of broken cardiac compensation. These tumors have been divided into the true and the false, the false being growth of the parent thyroid and attached to it by a pedicle. The true are thyroid tissue which may be attached or free, and may be single or multiple.

The patient whose case I report was admitted to my service at the Kings County Hospital, Brooklyn, N. Y., August 1 of this year, with signs of arteriosclerosis and of broken cardiac compensation; he died August 15 and an autopsy was performed.

On admission the patient stated that he had always enjoyed good health and had never been treated for any illness other than some of the minor diseases of childhood. The present illness began six months before admission to the hospital, with slight pain in the precordium, dyspnea on slight exertion, and during the past few weeks swelling of the legs after being up all day, with the swelling disappearing upon lying down.

During the patient's stay in the hospital, which was 15 days, he complained only of the difficulty of breathing; he became weaker, was irrational the day before he died, and without any evidences of pain or discomfort became unconscious and stopped breathing.

The physical examination showed an arteriosclerotic man of apparently 66 years of age, dyspneic, somewhat cyanotic, propped up in bed because of less dyspnea in the upright condition. The man presents a picture of cardiac incompetence, the face is emaciated, and the superficial veins of the face and neck are moderately engorged. Examination of the eyes, ears, nose, and mouth shows a condition commensurate with his age. Examination of the neck shows a slight fullness on the right side above the clavicle near the sternum. There is marked pulsation of the vessels of the neck on both sides. There is no tracheal tug; no difficulty in swallowing.

On inspection of the chest we note the dyspnea, the emaciation of the patient, large, tortuous, engorged superficial veins of the right side of the thorax, and large, engorged superficial veins of the right arm and hand. The veins of the left arm are over-full of venous blood, but not as full as those of the right arm. There is also a moderate edema of the right arm and hand.

Upon examination of the heart we find the area of cardiac dullness enlarged; the heart is enlarged downward and outward; the apex beat in the sixth interspace, outside of the midclavicular line; the apex 18 cm. to the left of the midsternal line. To the right there is an area of dullness blending with the area of dullness of the base of the heart and aorta, extending below to the fourth rib and to the right midclavicular line. Surrounding this area of dullness the percussion note is almost hyperresonant. The breath sounds are transmitted more distinctly over this area. There are signs of a moderate amount of fluid in the right pleural cavity. The heart sounds are of poor quality, rapid with a marked irregularity. There is a systolic murmur at the apex which is not transmitted to the axilla; there is also present at the apex a presystolic murmur. The second pulmonic sound is roughened and slightly prolonged. The second aortic sound is of a poor qual-

ity. The clinical impression is of enlarged heart with broken compensation and a tumor in the right chest cavity.

The accompanying diagram (Fig. 1) shows the physical findings in the chest:

The abdomen is relaxed; there is no tenderness and no free fluid in the abdominal cavity. The liver, which is easily felt, is enlarged and extends to the level of the umbilicus. The spleen is not enlarged. There is marked edema of the legs and of the scrotum.

While under observation the patient's urine was that of arteriosclerotic kidneys. His blood pressure was the same in both arms, systolic pressure 225 and diastolic pressure 110, the systolic being higher than normal. There was always marked venous stasis. Examination of the blood showed 3,160,000 red blood cells, with 50 per cent. hemoglobin, 9400 white blood cells with 80 per cent. polys and 20 per cent. small mononuclear cells. The sputum was negative for tubercle bacilli. The blood and spinal fluid gave negative Wassermann reactions. The spinal fluid was not under pressure when obtained, and examination of it showed nothing abnormal.

An *x*-ray picture of the chest, Fig. 2, shows the presence of a tumor as outlined by the physical findings.

At autopsy, upon opening the body a large amount of straw-colored fluid was found in the right pleural cavity; no fluid was found in the left pleural cavity or in the pericardial sac. The peritoneal cavity contained a large quantity of dark clotted blood and free blood, which came from a rupture of the transverse colon with the accompanying hemorrhage between the layers of the mesentery. The transverse colon for a space of six inches where it passed beneath the stomach was much thinned out as if rubbed between two hard surfaces and was ruptured in one place. The stomach and intestines otherwise were negative upon gross examination; on microscopic examination the specimens showed sclerosed blood vessels and connective tissue. No evidence of any growth or irritant could be found. The liver was increased in size and showed fatty degeneration. The kidneys were small and sclerotic.

In the mediastinum, remains of the thymus were not present. There was present a pear-shaped cystic enlargement of the thyroid gland not adherent to any structure, nor pressing on the trachea. It extends downward to press upon the transverse aorta, which it flattens out slightly. The tumor measures from above downward 14 cm.; from side to side, 8 cm., and from

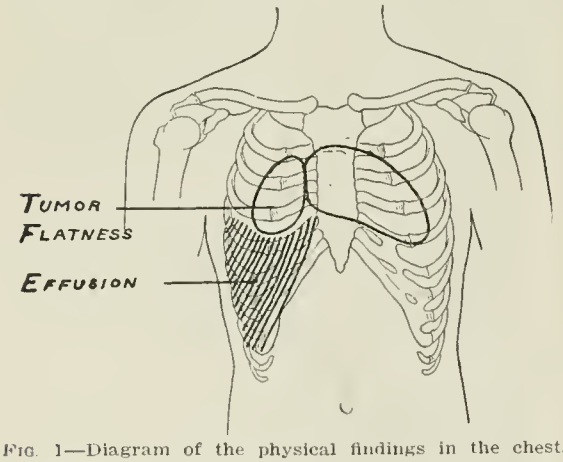

FIG. 1—Diagram of the physical findings in the chest.

before backward 6.5 cm. The outer covering is quite smooth. The aorta is not damaged.

The heart is large and flabby. The epicardial fat is increased in amount. On section the valves of the right side present no roughening, but are relatively incompetent. There is some thickening of the mitral valve, which is incompetent. On section of the heart muscle several areas whitish in appearance are noted. There is present sclerosis of the coronary arteries.

This patient presents an interesting pathological condition not commonly found. How much this condition contributed to his death can be surmised only on the basis of how much additional strain it caused to a poorly nourished sclerotic heart. The condition of general arteriosclerosis was well marked, and the immediate cause of death was hemorrhage from the rupture of a thin sclerotic transverse colon involving one of the large blood vessels. The patient at no time complained of abdominal distress nor showed physical evidence of impaired intestinal function.

FIG. 2.—Roentgenogram of the chest, showing the outline of the thyroid tumor.

108 PROSPECT PARK WEST.

LOSS OF CONSCIOUSNESS AND AUTOMATISM IN INEBRIETY.

BY T. D. CROTHERS, M.D.,

HARTFORD, CONN.

SUPT. WALNUT LODGE HOSPITAL.

DURING the past year in several instances where the question of responsibility was referred by the courts to medical men this question called for an answer: Can an inebriate or a person under the influence of alcohol lose consciousness of his surroundings and of the nature of his acts and go on automatically ,giving no impression of his real condition? In other words, is it possible for an inebriate, not intoxicated in the general sense, to be unconscious of the nature and consequences of his acts?

The answers given to this question were so uncertain and vague as to indicate a strange lack of knowledge. Thus in one case a man who had used spirits continuously while conducting his farm work and giving no evidence of defective consciousness by the nature and consequences of his acts shot a near friend who was crossing his farm. He was arrested, placed in jail, and a few hours later awoke claiming not to have any consciousness of his con-

duct from a point of time a day before the homicide, up to the time when he awoke in jail. The physicians treated this statement as fiction and declared it impossible; a third one thought that it might possibly be a pathological state, but could give no reason or explanation. The man was executed, but up to the last moment protested that he had no recollection of the crime or the events occurring during this period, and there was no reason or motive for this act. In the second case a carpenter who had been drinking steadily for several years, but never to intoxication, shot his wife at the dinner hour and went back to his work and later was arrested and taken to the station-house, and the next day woke up and when told what he had done exhibited profound astonishment. He claimed no recollection of the event or any consciousness of his acts for several days before the crime. He also claimed to have had blanks of memory in the past, during which he was unable to recall the events of the day. As he had worked regularly during these times and his conduct had been natural and reasonable there seemed to be doubts of this condition beyond his own statements. On the trial this defense of unconsciousness was treated with contempt, and the medical witnesses swore that it was impossible to lose all memory and consciousness, without making it manifest in conduct. In 1879 I published the first study of this peculiar condition, which was termed at that time cerebral trance.

In 1877 and 1878 Dr. Hughlings Jackson published in the West Ridings Hospital reports an account of similar cases following epileptic attacks. Dr. Carpenter of London had mentioned such cases and called attention to their responsibility, but these occurred in epilepsy. My study of these cases was the first that was made of this condition appearing in inebriates. In 1880 the late Dr. George L. Beard made a careful study of such cases with an explanation of the phenomenon and from that time to the present many startling examples have been published and the reality of this mental condition has been accepted. Notwithstanding this, the courts and many medical experts have regarded it as a doubtful state and a refinement of science, having for its purpose to increase the irresponsibility and excuse the punishment of criminals. Within the last year the subject has come into prominence again, and Dr. Sullivan, an English alienist, has taken up the matter, pointing out the physical conditions of persons in this state and showing that it was not only possible but a reality which may be demonstrated by facts that would admit of no other explanation.

The following recent cases bring out the facts more clearly than any attempted description of symptoms. A farmer, fifty years of age, with no history of hereditary condition, who had suffered from sunstroke when about thirty years of age, and had since that time complained of weakness and invalidism. Soon after the sunstroke he began to drink beer, and ten years later used spirits regularly every day. On several occasions he had been intoxicated, but recovered quickly and seemed more careful than ever to restrict the amount of spirits used to a minimum. He was arrested for placing obstructions on the railroad track for the purpose of wrecking a train. He was arrested four days after the act, taken to jail and claimed to have no recollection of what he had done and no idea of the purpose and object in doing this. On the trial it appeared that he had lived regularly and was quiet and retiring in his habits, drinking spirits regularly, and was considered a sensible man. His conduct to his family had been uniformly kind, consistent, and reasonable. During the last five years several eccentricities and unusual acts occurred. One of them was to stop work suddenly, go off suddenly to a neighboring pond, take a prolonged bath, then return to the barn and fall asleep on the haymow; a few hours later awakening, going on with his work without explanation or reference to what he had done. On two occasions during the winter preceding the crime he arose in the night, went out to his barn, drove out his cattle, cleaned the stables, put the cattle back, fed them and returned to the house, and the next morning did not seem to know that he had done this. When told, he attempted a childish explanation or reference and became more reserved than ever.

On the evening of the crime he went as usual to look after his stock, but did not return for several hours. Coming in exhausted he drank spirits and slept far into the next day. When asked where he had been he said "To the barn," but gave no explanation why he had remained so long away. The crime showed great cunning and judgment. The obstructions were placed on a curve in such a way that they could not be seen far away, and completed at a time just before the passing of an express train, and after the night watchman had inspected that part of the road. The obstruction appeared to be the work of more than one man, and particularly of someone very familiar with the conditions. The engine was wrecked and the engineer killed. The detectives found that he had gone to the place with his barn lantern, and had been seen by several persons going and coming, hence it was traced clearly to him. He stoutly denied all knowledge of the circumstances.

On the trial there could be no motives proven; he had never expressed any anger at the road, having seldom traveled from home and rarely on this road. The prosecution claimed that it was purely malicious and the defence of no recollection was absurd. In a more detailed study it appeared from his own statements, which were confirmed by those of his friends, that he had had blanks of memory during the last two years and that his statement of no recollection must be true from his conduct in many minor things.

It was noticed that at times he seemed to be deeply absorbed in reading the details of accidents and sensational crimes over and over again, never mentioning them afterward; at other times his reading was of a different character, principally novels and magazines. It was the opinion confirmed by the expert for the defense that during one of these blank periods he must have read of a similar effort to wreck a train in some part of the country, and this had so impressed itself on his mind that in this blank state he committed the same act. Probable the ingenuity and judgment displayed was merely following the details as given in the paper.

This was treated with doubt by the court and the

witnesses for the prosecution, and he was convicted, but died soon after being sentenced of some acute disease. Several physicians swore on the trial that the continuous use of alcohol would not impair the mind or break up the consciousness of his surroundings and acts, unless accompanied by symptoms of delusion, delirium, and other mental defects. They also swore that his conduct during this condition would of necessity give indications of his mental state and that had he suffered from blanks of memory he could not have acted consistently and sanely.

A second case in which a will was contested brought out the following facts: A man of middle life, actively engaged in manufacturing, died suddenly and left a strange will, which was contested on the ground of alcoholic blanks, or loss of consciousness of his conviction at the time the will was written. It appeared that he came from a neuralgic family, in which several members, both in the direct and indirect line of heredity, had been insane or paranoiac. He had lived a regular, temperate life up to forty years of age, when after the death of an only son he began to drink spirits. For the following fifteen years up to the time of his death he drank regularly, although never intoxicated or apparently unable to transact ordinary business. It was his custom to visit his agent in New York monthly and go over the accounts and arrange for the purchase of materials and the sale of the manufactured product. On all these occasions he showed judgment and clear discrimination of the conditions and the requirements necessary. At one of these periods, after finishing the business, he called in a lawyer and had an elaborate will drawn up, which contained details and disposition of his property, that seemed foreign to his usual thought and conduct. On several occasions, during the year this will was written he had persisted in manufacturing a greater quantity of a certain product than ever. This overproduction proved to be a loss; on another occasion it was a gain. He became interested in a mine, investing money in it, which was a very unusual thing for him. He had, while in New York, purchased expensive diamonds for his wife, and when chided about this claimed he had no recollection of it and seemed annoyed. The family physician had been frequently called to treat him for imaginary conditions, which seemed of an hysterical character. The next day when seen he did not remember to have asked advice from the physician. When advised to give up the use of spirits he promised to do so, signing the pledge and showing great interest to carry out the advice, but continued to use spirits as before, and claimed that he did not remember to have made any promises of total abstinence.

On the trial the medical testimony, as usual, differed widely, but the will was finally set aside. In both these cases the physician hesitated about the possibility of the paralyzing action of alcohol. The increased heart's action following its use was considered a stimulant and its injury to the mind thought impossible unless it was manifested in pronounced insane acts and thoughts.

The recent modern researches into the action of alcohol on the higher brain centers show that its continuous use, even in small doses, not only diminishes mental activity, but lowers the memory powers, and that its accumulative effect shows unconsciousness and memory of events with more or less certainty in all cases. We cannot tell how far this damage to the memory extends, but the frequent claims of amnesia and acts which show this condition really confirm it.

The central fact is of extraordinary interest, that normal consciousness and memory of events should be clearly obliterated for a time and then return again. It is a very common experience among moderate or excessive drinkers to have periods of amnesia or blanks of memory which later clear up, and the acts committed during this period are recalled. This occurs in the pronounced toxic states of alcohol, thus: a man who is intoxicated may not recall what he said or did just before and during the period of stupor and delirium. Some time afterward his memory returns and the acts which soon after were not recalled later become clear to him. In these conditions the blank period was associated with stupor, delirium, and strange conduct so that the real condition could not be mistaken. But in these particular cases that I am describing there was no marked unusual conduct or indications that the victim was not conscious of all the events of his surroundings and their relation to him.

In one of the cases which I reported, a traveling man, who drank steadily, ceased to remember after a certain point in his journey and awakened eight days later in a distant city. The interval to him seemed only as a single night or a few hours. During this time he had pursued his customary work, soliciting orders for goods, talking with customers in a rational way, and no doubt thinking with them, but his real condition was not apparent to anyone. He was literally acting automatically, doing accustomed work, but entirely unconscious of it, although writing letters daily to his firm and giving accounts of the business of the day. On recovery all this interval was a blank and only by memorandum on his daily notebook was he able to determine how long he had been thus, where he had been, and what he had done.

In a number of studies which I have made of this peculiar condition there appeared to be three groups or divisions, one in which the mind in this condition, acted along accustomed lines of thought and action; a second group in which the mind displayed unusual ranges of thought and acts quite different from the ordinary custom; third, a class of cases in which the criminal or homicidal impulse was prominent at this time.

Cases illustrating these different conditions have been studied. The first or third groups have come into greater prominence than the second. The first group includes persons who go about performing accustomed work and later seem to have no recollection of it.

A prominent case of this class was that of a railroad conductor, who drank at night before retiring and frequently had no recollection of waking up in the morning, taking his train to its destination and sometimes returning before he became conscious of what he was doing. He would then ask the brakeman what had happened and be unable to recall anything of the ordinary duties of his work. I have met a number of cases of this class who lost all recollection after a certain time, for indefinite

periods, during which they seemed conscious, but on awakening and being told what they did became greatly excited and were placed under my care for treatment.

The second class during this blank state do unusual things, talk and act in a manner which makes their friends suspicious of their natural condition, and yet no one suspects that they are not conscious and to a degree responsible for their conduct. Many of these cases after drinking display eccentricities of character, whether of a very emotional or depressed nature. One such man after drinking steadily for a few weeks will become intensely religious and visit clergymen, attend meetings, ask the prayers of his friends, show extraordinary anxiety for the world to come, and then he will suddenly change, go back to his old life, and seem not to have any recollection of what he has done.

Another man in this condition manifested great political anxiety about officers and politics. One day in his zeal he had a personal conflict with a doubter and immediately awoke and denied all recollection of having said anything and could not recall any purpose or plan in his conduct. A number of business and professional men, after a period of continuous drinking show great emotional changes and do strange things at the time, then later deny all recollections of the occurrences.

No medical study is made of these cases for the reason that the theory of vice and viciousness is so pronounced in the public mind that these conditions are explained as moral lapses.

The third class in which criminal acts and conduct resulting in loss and injury to others are prominent, but here the same medical theories prevail in the court room and the question of responsibility is treated on the old-time theory that inebriety is always voluntary and the use of alcohol as a beverage is always attended with consciousness and sane reasoning. Hence the commission of a crime under the influence of this drug is regarded as an aggravation and all question of responsibility is treated with doubt and suspicion. When such a claim is made both experts and non-experts attempt to answer the question of responsibility by comparing the history of the crime and prisoner with other types of insanity. The absence of delusion, allusion, and delirium or marked mental feebleness are regarded as evidence of mental soundness. The statement of the prisoner is always suspicious and regarded as an excuse, and where no effort is made to study the previous mental condition before the crime was committed, such as the facts of his surroundings and living, the expert accepts the teachings of the law concerning his condition without effort to understand the defects present.

The late Dr. Beard, in discussing the question of unconsciousness during this condition, said that there was a degree of consciousness present in all these cases, but that it was not fixed in the memory and hence quickly forgotten. "Consciousness is one thing; remembering past consciousness is quite another thing. There is a plane of consciousness below which it is unrememberable and above which it is more or less rememberable. This whole matter is one of degree, in which we forget much of our past life sooner or later."

The peculiarity of these cases is that events and surroundings are quickly forgotten; then later this blank state passes away. During this time the person may act rationally, but not recall events. There is one fact clear which should never be forgotten—that this automatic condition is found associated with some form of neurosis, either induced by alcohol or existing before alcohol was used. In all chronic conditions where alcohol is used either in large or small quantities it may be found, and the person may be aware of this condition and, if he is, conceals it; in others, it is only dimly recognized.

This particular form of automatism follows in persons who use spirits continuously or in the so-called moderate drinkers. Some instances have been studied, seen in the periodic drinkers, after an excessive attack of acute poisoning from alcohol, which resembles epilepsy and very likely is some obscure form of this disorder. For many years blanks of memory and consciousness have been noted following epileptic paroxysm, but usually this condition was characterized by symptoms indicating suspension of brain activity in certain directions. When this condition appears in the inebriates it is more obscure and requires careful study to determine.

There can be no question that, pathologically, certain areas of the brain are paralyzed. Functional activity is arrested and cut off. It probably occurs in a very large proportion of cases, but is of so slight a degree as not to attract attention. In some studies I have concluded that at least 7 per cent. of all drinkers have blanks of memory, some of which they were able to recall later; in others, the events occurring during this blank were never apparent after. The period of intoxication associated with stupor is always attended with loss of consciousness, particularly just before or after the stupor has passed off.

I think the following conclusions may be stated as confirmed by all careful clinical studies: First—Cerebral automatism and loss of consciousness particularly is a common symptom, especially in the later stages of persons who drink spirits to excess occasionally. During this period there appears to be general consciousness in the acts and conduct which is not remembered afterward. This period may last for a few hours to several days. Second—There must be pathologically as well as psychically some profound disturbance and palsies of certain brain centers, in which registration of events and impressions of the senses are absent and with this, of necessity, must be impaired judgment and lessened responsibility. Third—This condition is usually found associated with a neurosis and psychosis either induced or existing before alcohol was used. The first conclusion rests on the statement of the person supported by collateral facts. The second is apparent from the conduct and explanation supporting it. The third form of grouping of the histories of different relating events.

The following recent case brings out a class of facts that are known to many persons, but have not yet been understood. A lawyer of eminence whose ancestors and family had all died of consumption came under my care for alcoholic delusion and general exhaustion. He was a nervous, passionate man, wealthy, of brilliant talents, ambitious, and a politician of much prominence. From early life he had

been a gourmand. Ten years ago, after an attack of typhoid fever, he began to use whiskey at meals and continued its use, not only at the table, but at all times and places. He was never seen intoxicated, but was constantly exhilarated under the use of spirits. His life was more or less irregular and he complained of exhaustion and occasional insomnia. He was constantly employed as a campaign speaker and lecturer. On one occasion after a protracted period of speaking he went to a lawyer's office and wrote a will, had it properly signed, saying he was going to die, and asked the lawyer to send the will to his confidential banker. One month later in a distant part of the country he made another will, giving minute directions as to the disposition of his body and the funeral services. A few weeks later he became engaged in a mining scheme of great magnitude, drew up preliminary papers, arranged details and sent them to his banker. On all of these occasions he seemed perfectly calm and reasoned clearly about the wisdom of these events. Finally, through the advice of friends he went to the seashore to rest, and there consciousness returned, and he had no recollection of writing wills or forming a company. These and many other events were blanks. He had been speaking night after night for a week at a time in a political campaign without any recollection of where he had been or what was said; then he became exhausted and would go to some friend's house and remain in bed for several days and wake up and ask them where he had been and what had happened. This man recovered, but there was a period of nearly a year in which his memory was a partial blank. During the past summer he has lived a very quiet life in the mountains, but recently has gone on the stump and resumed his drinking. In all probability the same blanks or loss of memory will appear, and no doubt this case is one of many whose real condition is unknown. The startling cases of crime, without motive or purpose and undefinable by any rules of courts and experts, undoubtedly belong to this class.

Thus a man who suddenly commits a crime or shows extraordinary credulity in business or does some very unusual act entirely inexplicable on any theory of commonsense or judgment may be, and most assuredly is, in this automatic condition. There can be no doubt that many persons are arrested for crime and offence against society and a large part of the business of the court is in the punishment of these poor victims for acts of which they are utterly unconscious.

The following is a summary of some of the facts which I wish to make prominent: Automatism in inebriety with loss of consciousness is not an uncommon condition, particularly in continuous or periodic drinkers. It is also seen in periodic cases as well as in epileptics and is a distinct palsy of the brain. All unusual acts or crimes committed by inebriates or hard drinkers should be studied, particularly where there is a possibility of loss of consciousness with alleged amnesia. When this condition is established the person is both legally and practically irresponsible for his conduct during this period, and his mental condition is one of great gravity, requiring immediate care and attention. No theories of vice, wilfulness, and moral causation should be considered by the physicians. It is a great question of facts and their meanings. Cerebal automatism and loss of consciousness is a pathological condition which must be studied from a scientific point of view to be understood.

MEDICINE AND THE MOON: BELIEFS OF OTHER DAYS.

By HOWARD D. KING, M.D.,

NEW ORLEANS, LA.

From the remotest periods of antiquity, the idea has prevailed that the moon exercises a certain and well defined influence in the causation of disease, and plays a prominent part in the development of nations, and in determining the destinies of the human race. Among the ancients the moon was viewed as an object of superstitious regard. The Hebrews held the moon in great religious and superstitious veneration, considering lunar influence superior even to that of the sun; in fact, the moon was worshipped as a Deity. The new moons, or the first days of the month, were kept with great pomp and ceremony as national festivals. The people were obliged to abandon work on those days. The feast of new moons was a miniature of the feasts of the prophets. The Jews who were not acquainted with the phenomena of eclipses, whether of the sun or the moon, looked upon them as evidences of divine displeasure. The Greeks consulted the different phases of the moon before contracting marriage; and the full moon, or the conjunction of sun and moon, were considered the most favorable periods for celebrating the ceremony, in view of the belief that the reproductive functions were under lunar influence.

The very ancient doctrines that menstruation and pregnancy are under lunar influence has many advocates. It is, undoubtedly, difficult to explain the great laws of nature insofar as periodicity in the female species is concerned, but it may be safely stated that the moon plays no part therein. The opinions held by medical men on the doctrines of lunar influence in pregnancy and menstruation have been remarkably discordant. The sceptical are unphilosophical in their scepticism, and the believers credulous in their belief.

The connection of the moon with the measure of time brought the planet into relations with the religious rites of ancient nations, as the Egyptians and Jews; and, also, to have given origin to the mythological ideas of a lunar influence on marriage and pregnancy. Among the older nations the general idea was that the lunar influence varied according to the age of the moon. Bombastes, the Egyptian Diana, was not equally favorable to parturient females and their offspring in her different phases.

To-day in Greenland there exist many superstitious notions concerning the moon. The Greenlanders believe that the moon visits their wives at stated intervals; and, that staring long at the full moon will make a maid pregnant.

Among the Jews the full moon was believed to be lucky, and the other phases of ill omen. For instance, the ancient Jews believed the full moon propitious to the new born child; but if the child be born in the increase or wane, the horns of the

planet cause death; or, if it survive, it will commit some terrible crime.

The Greeks and Romans entertained ideas similar to the Hebrews respecting the lunar phases. The general opinion seems to have been that the moon was propitious in proportion as its luminous face was on the increase. The ancient Greeks considered the day of the full moon to be the best day for marriage. Euripides makes Agamemnon answer when asked on what day he intends to be married:

"Οταν σελήνης εὐτυχὴς ἔλθη κύκλος.

("When the blesséd season of full moon is come.")
Iphigenia, Act. V.

Hesiod declared that the fourth day of the moon was favorable, but the eighteenth was bad, especially to females. Aristotle maintained that the bodies of animals were cold in the decrease of the moon, and that the blood and humor are then put in motion, and that to those revolutions he ascribes the various derangements peculiar to women.

Lucilius, the Roman satirist, states that oysters and echini fatten during lunar increase, which also, according to Gellius, enlarges the eyes of cats; but that onions throw out their buds in decrease of the moon, and wither in its increase, which induced the people of Pelusium to avoid their use. Horace also noted the superiority of shellfish during the moon's increase.

Pliny was cognizant of the lunar influence on shellfish. He also adds that the streaks on the livers of rats answer to the days of the moon's age,* and that ants never work at the time of the lunar changes. Pliny also informs us that the fourth day of the moon determines the prevalent wind of the month, and confirms the opinion of Aristotle that earthquakes generally occur in the new moon. This same observer declares that the moon corrupts all dead carcasses exposed to its rays, and produces drowsiness and stupor in those who sleep under its beams.† Pliny further declares that the moon is nourished by rivers, as the sun is fed by the sea. Galen asserts that all animals who are born when the moon is falciform, or at the half quarter, are weak, feeble, and short-lived; whereas those who come into the world during the full moon are healthy, vigorous, and long-lived.

The Spartans also considered the moon to have great influence, and no motive could induce them to enter upon any expedition or march against the enemy until the full of the moon. The Greeks and the Romans believed that the moon presided over childbirth. The patricians of Rome wore the figure of a crescent upon their shoes to distinguish them from the lower classes. The crescent was called *lunula*. Herodotus records that when the Lacedæmonians visited Athens, after the battle of Marathon they waited until the moon had passed its full before they continued their march (Erato lxx). The ancient alchemists endeavored to localize planetary influences, maintaining that the *heart*, which represented, according to their physiological ideas, the vital spark, was under the special protection of the *sun;* that the *brain* was regulated and controlled by the *moon;* that *Jupiter* presided over the *lungs; Mars* over the *liver; Saturn* over the *spleen;* that *Venus* took the *kidneys* under her gracious wing, and that *Mercury* sat in judgment upon the *reproductive organs.*

Thus it will be seen that from the earliest periods in the history of the world, and even up to the present day, the idea of the phenomena of organic life being subject to planetic influence has held sway among the most enlightened and philosophical men. The following passage proves that the greatest of the Roman satirists was bitten by this belief:

"Ut mala quem scabies aut morbus regius urget
Aut fanaticus error, et iracunda Diana
Vesanum tetigisse timent fugiuntque poetam.
Qui sapiunt."

Horace, *Ars Poetica.*

It is now well established as a scientific fact that the moon has no influence on temperature, rainfall, or any other meteorological element, or on plant growth. Plant growth depends upon temperature, light, humidity, and plant food (both in the soil and in the air), and its availability. As regards light stimulus, the moon's influence on plant growth is absolutely *nil.*

The moon appears to have called forth the fire and sublimity of poetic genius in all ages, and in all climes. Most of the great dramatists and epic poets have embodied in their immortal creations a belief in the influence of the moon. The works of Shakespeare, Spenser, Beaumont, Fletcher, Ben Jonson, Byron and Shelley are replete with passages in relation to this subject. Shakespeare, whose intuitive insight into the subtle workings of the human heart and passions was most keen and intimate, has pointedly alluded to the moral influence of the moon on the human heart and intellect. In "Twelfth Night," Olivia, after apostrophizing Viola as a "most radiant, exquisite, and unmatchable beauty," exclaims: "I heard you were saucy at my gate, and allowed your approach rather to wonder at than to hear you. If you be not mad, be gone! If you have reason, be brief! *'Tis not that time of the moon with me to make one so slipping in dialogue.*"

Again, in the play of "Antony and Cleopatra," Enobarbus, after entering Cæsar's camp, thus appeals to the moon:

"Be witness to me, O thou blessed moon!
When men revolted shall upon record
Bear hateful memory, poor Enorbarbus did
Before thy face repent."

After which, he adds, previously to expressing his deep contrition for his revolt against Antony:

"*O sovercign mistress of true melancholy,*
The poisonous damp of night dispunge upon me;
That life, a very rebel to my will.
May hang no longer upon me."

In "Othello" after the death of Desdemona, when Emilia enters the chamber to announce the foul murder of Roderigo by the hand of Cassio, the Moor, crushed to the earth by an accumulation of miseries, exclaims in the agony of his soul and in the bitterness of wild despair:

"'Tis the very *error of the moon,*
She comes more near the earth than she was wont,
And makes men mad."

*Research work in a rodentological laboratory during a plague outbreak shows this observation to be untrue.

†An experience as ship surgeon in southern tropical seas, where crews frequently slept on deck during full moon, convinces the author that moon rays have no effect whatever on the human individual.

In "King Richard the Third," the Queen, after rushing, while in a state of profound distraction, into the presence of the Duchess of York, to announce the death of the King, passionately exclaims:

"Give me no help in lamentation;
I am not barren to bring forth laments;
All springs reduce their currents to mine eyes,
That I, being govern'd by the wat'ry moon,
May send forth plenteous tears to drown the world."

Milton frequently alludes, in "Paradise Lost," to the pernicious effects of the moon. He speaks of

"Demoniac frenzy, moping melancholy,
And *moonstruck madness.*"

In Ben Jonson's "Alchemist" Tribulation says:

"But how long time,
Sir, must the saints expect?"

To which Subtle responds—

"Let me see,
How's the moon now? Eight, nine, ten days hence,
She will be silver potate; then three days
Before to citronize,—some fifteen days."
Act III, Scene 1.

In the sixth chapter of Scott's "Fortunes of Nigel," David Ramsey gives utterance to the following prophecy upon the birth of the Duke of Buckingham:

"Full moon and high sea,
Great man shalt thou be;
Red dawning, stormy sky,
Bloody death shalt thou die."

The notion of planetic influence has not been confined alone to the fanciful creations of the poet. It has existed among barbarous, uncivilized, and unlearned peoples, who were profoundly ignorant of the views propounded by the ancient astrologers, or by the medical writers, who had somewhat engrafted the study upon that of astrology and astronomy. Medical science could not escape being involved in these beliefs. In referring to the alliance which formerly obtained between the two sciences, there can be no doubt that the application of astrology to medicine, though it was soon perverted and debased until it became a mere craft, originated in actual observation of the connection between disease and season. That these beliefs influenced medical thought can be easily seen by a reference to Matthew XVIII, verse 13, wherein is described a person as falling often into the fire, and often into the water as being affected (σεληνιάζεται) by the moon. Trallian, employing the same word, terms *cpileptics,* σεληνιακόι. Apuleius, a Latin author, also terms epileptics *lunatici.* For those suffering from colic it was the custom of Trallian to direct that a magical ring be worn on the seventeenth and twenty-first day of the moon.

Hippocrates imbibed so strong a belief regarding the effect of the celestial bodies upon the vital manifestations that he expressly recommends no physician to be entrusted with the treatment of disease who was ignorant of astronomical science; and he advised his son, Thessalus, to study the science of numbers and geometry, declaring that the "rising and setting of the stars have great effect upon the distempers." (Epist. ad Thessalum de aere, aquis, et locis.)

The critical days, or crises, as they were termed, were said to correspond with the interval between the moon's principal phases. The crises which Hippocrates describes by the words *imperfecte judica-* to which he applies the terms *perfecte judicabantur bantur* were the *intermediate lunar crises;* and those were *final inter lunar* crises. Galen also was an adherent of the Hippocratic idea. Hence the lunar periods were said by him to be connected with the exacerbation of particular diseases. In this connection it might be stated that the terms *luna-*tic that the moon exercises a decided influence on the and lucid are commonly based on the hypothesis insane.

Medicolegal Notes.

Statute to License Optometrists Held Invalid.—Appeal was made from a conviction of practising optometry without a license, in violation of the Illinois statute, Laws of 1915, p. 695, entitled "An act to regulate the practice of optometry in the State of Illinois, and fixing penalties for the violation thereof." The facts proved were as follows: The defendant was a graduate of McCormick Medical College and of the ophthalmic and optical department, but was not licensed to practise optometry in that State. A woman who was a licensed optometrist was sent by a member of the State board of optometry to the defendant's office to find out whether he would violate the statute. She asked to have her eyes tested for reading, and he put on her head a try frame, in which he could place different lenses to see whether she could read letters which he placed at a distance, and when he found lenses that suited her she contracted to pay him $12.50 for glasses, paid him a dollar, and took a receipt. The question at issue was whether the statute was valid. It provides for a State board of optometry, which may examine applicants and issue licenses, and exempts from examination any person who has practised optometry at any established place of business or practice for three years, who may be licensed on payment of $5.

The court said that while there is much uncertainty as to what acts are included in the practice of optometry, it would assume that what the defendant did was such practice. It held that if the changing of lenses until the customer was suited, or placing letters at a distance to be read, is measurement of the power of vision and the adaptation of lenses, it is no more than the measurements made by any person who undertakes to fit a person where the person himself decides what answers his purpose. Such measurements, if they are so called, have no relation to the public health, comfort, safety, or welfare, such as to require a course of previous study and an examination and payment of a license fee. The police power of the State may be exercised for the regulation of any trade, calling, or occupation for the purpose of securing the public health, safety, and welfare, but if an act has no reference to either, the personal liberty of the citizen to pursue any avocation cannot be limited or restricted. Here no reason was given by counsel how the comfort, health, welfare, or safety of society is to be promoted by requiring a license for such acts as were done by the defendant. A statute which singles out a particular class of persons and imposes burdens on them from which other similar classes are exempt violates their constitutional rights, and cannot be sustained. The court said: "We do not say that it is beyond the power of the General Assembly to enact a statute requiring a previous course of study and an examination of applicants to practice the calling or profession of examining the eye to ascertain if there are defects which can be remedied by the use of lenses, the determination of the accommodation and refraction states of the eye, the range and power of vision and abnormal conditions, and the adaptation of lenses to correct defects or to require a license to practice such calling or profession; but the act now in question, as construed by the parties and counsel, is not within the scope of the powers intrusted to the General Assembly." The act was therefore held invalid.—People v. Griffith, Illinois Supreme Court, 117 N. E. 195.

Military Medicine.

PNEUMONIA IN A CAMP OF FRENCH PRISONERS IN GERMANY.

MALLIÉ, a French army surgeon, improved the opportunity which befell him of reporting on 244 cases of pneumonia as they occurred in a prison camp in the earlier years of the war (*Journal de Médecine de Bordeaux*, October, 1917). The same number of Russian captives presented but 116 cases during the same interval. The picture of the disease was absolutely classical—men in full health complained of a severe pain in the side accompanied by a sudden rise of temperature (about 104° F.), dry cough, and rusty sputum, with the usual physical signs. As a rule, these cases ended in a sudden crisis, with defervescence and free sweating. The incidence of the disease was about 20 per 1000 soldiers. In peace times army morbidity is from 4 to 6 per 1000, while in soldiers in campaigns the infrequency of pneumonia is proverbial. Hence to explain so high an incidence as 20 per 1000 in the prisoners we must invoke the agency of special factors. The observation period may be divided into early and late. In the first 3 months of the war 50 cases developed, while in the last 4 cold months the number was 130. The increased incidence seemed to be due partly to the weather and partly to a restriction of the diet. With return of the warm weather the morbidity fell off notably. In regard to cardiac complications, these were as good as absent; while the gastrointestinal tract maintained its integrity in the great majority of cases. On the other hand, a septicemic factor was plainly in evidence, as shown by hyperpyrexia, involvement of the nervous system, coexisting lesions, low resistance, as shown by spread of the disease to the pleura and lung tissue, awakening of acute tuberculosis, etc. The involvement of the pleura appeared to determine a pleural localization of tuberculosis.

In France the average pneumonia patient is in good general condition when stricken, and when the disease attacks a victim of hardships and privations the prognosis should be unfavorably influenced; but the author lost but 10 of his 244 patients, or 4 per cent. Of 116 cases in 12,000 Russian prisoners, 11 ended fatally (10 per cent.). In order to account for this difference the author states that the French received aid from home during part of the observation period—additional clothing and food. The low French mortality from the disease will necessarily be increased at a later period from the secondary tuberculosis. The author treated his patients with cupping, milk diet, and the daily injection of camphor oil, from 30 to 40 c.c. in 3 injections. After defervescence, Fowler's solution was given. Respiratory gymnastics were begun 10 or 12 days after recovery, with thermometer control.

Care of Disabled Soldiers in France and Germany.—The question of how to deal with soldiers disabled in war, so as to render them so far as possible self-supporting, was first grappled with in France and Germany. In the new publication entitled *Recalled to Life*, the work which is being done for the disabled soldiers in these countries is dealt with exhaustively.

France.—With respect to restorative treatment in France, the work of the Military Medical Service (*Service de Sañté*) has been to set up centers for physical and mechanical treatment in connection with the principal military hospitals in all parts of the country. There is a tendency for centers to specialize in certain branches of treatment one center caring especially for the deaf, another for the needs of the one-armed, while special attention is paid to the treatment of the blind at Paris and Bordeaux.

In June last the Under Secretary of State published the broad outlines of a new scheme for securing closer cooperation between the physical and occupational and training centers. The functions of the centers under this new scheme will be: (1) To furnish a man with the most suitable apparatus. (2) To provide at one and the same time functional and technical training. (3) To establish or develop workshops in which surgical apparatus and artificial limbs may be manufactured, altered, or repaired, etc. At the present time, the Centers for Physical Training are under the control of the Military Medical Service, while the Occupational Training Centers are carried on by public authorities or private societies, and thus some difficulty in carrying out this program as regards existing institutions was anticipated. It is believed, however, that these difficulties are not insuperable, provided all concerned can be convinced of the absolute necessity for coordination.

So far the treatment of the deaf, the system known as a "reeducation auditive" has found some energetic advocates. It consists in stimulating the remaining sense of hearing by constant repetition of certain sounds. The method most in favor is to provide careful instruction in lip reading for those whose deafness is incurable. Since the spring of the present year a course for deaf soldiers has been carried on at the National Institute for Deaf Mutes in Paris. The men are boarded and lodged in the military hospitals, and attend the institution daily for instruction. The Military Governor of Paris has authorized a special course of training in voice production and speech for those who are dumb as a result of wounds, shock, etc.

The provision of suitable artificial limbs has been somewhat of a stumbling block in France as in all the countries at war. The ideal artificial limb should be not so much ingenious as serviceable. Dr. Bourreau of the Orthopedic Center at Tours has made a prolonged study of the best apparatus for enabling men who have lost an arm to resume work. He estimates that out of every hundred men who undergo amputation thirty-six lose an arm or hand and that there may well be, by the end of the war, 30,000 men in need of the kinds of apparatus on which he is working. His plan is to study in workshops, factories, etc., the part played by the left hand in the case of workmen engaged in various operations. He then designs an instrument capable of acting as substitute for the left hand. Men who have lost the right hand are, first of all, taught to accuston the left hand to perform the functions of the right hand. As a result of these studies and ex-

periments a great variety of mechanical aids, which are in effect tools adapted to various purposes, have been devised.

Dr. Jules Amar of the Conservatoire des Arts et Mètiere, has also worked out and applied special forms of treatment for men who have lost their limbs. Some years before the War Dr. Amar was asked by the French Government to make a scientific study of the relations between the physiological efforts involved in various forms of industrial work and the results produced. The conclusions drawn from these studies have been communicated by Dr. Amar from time to time to the Academy of Science. He claims that by retraining the nerves and muscles of the stump it is possible to increase the sense of touch and strengthen the muscles to a degree hitherto unsuspected. He recommends that every man who has lost a limb should undergo special physiological treatment and training. His experience has shown that such treatment not only improves the physical condition, but prevents nervous degeneration; at the same time that it enables the men in many cases to obtain extraordinary mastery of an artificial limb. This is of special importance where blindness is added to the loss of one or both hands, and even where a blind man is not otherwise injured, the reeducation of the sense of touch by means of apparatus designed by Dr. Amar has proved of incalculable service.

A very large proportion of the rank and file of the French army is drawn from those classes known as "cultivateurs," owners of land, tenant farmers, and agricultural laborers. It is considered that special efforts should be made, including training where necessary, to induce men to return to the land. Several schools have been provided for the purpose of such training, and it is interesting to note that many blinded soldiers, if not otherwise disabled, can take up agricultural work. In February, 1916, a special board, known as the "Service de Placement," was created by the Ministry of War: (1) To centralize the information available as to the number of disabled men seeking employment and to act with the local labor bureaus in finding employment; and (2) to study the best methods of utilizing the labor of the disabled in the interests of the economic life of the country.

The care of blinded soldiers has received careful attention in France since the earliest months of the war. The organization for their welfare has made more progress, perhaps, than that designed to help any other class. The state has caused to be set up fifteen institutions, one in Paris and the remainder in fourteen large provincial towns, mostly in connection with previously existing schools for the blind. There is accommodation in each of these institutions for about thirty men. As soon as his condition allows, a blinded soldier is sent to the school nearest his home or place of birth.

Germany.—Knowledge of what has been done for the care and rehabilitation of German soldiers disabled in war is necessarily not so accurate as that of similar doings in the Allied countries. All information in this direction has been procured from German sources and is based on articles which have appeared in German periodicals.

Regarding the provision of artificial limbs, the German military medical authorities have issued instructions that no mutilated man is to be discharged from the army until he has thoroughly mastered the use of the artificial limb supplied to him by the authorities. Many artificial limbs have been devised, but none seems to have acted as a really efficient substitute.

Men are instructed in the German hospitals and convalescent homes. In a large number of hospitals the military authorities have themselves provided workshops, in which men work under medical supervision, it having been found that the exercise thus secured is more beneficial than mere remedial movements. It has been also found that iron and wood workshops can be run on a self-supporting basis in nearly all hospitals, so that the work done by the men has generally an economic value. In addition to workshops, which serve the double purpose of exercise and training, the military medical authorities afford facilities for any other kind of instruction which may be offered by educational or welfare societies.

No information is available as to the actual number of German hospitals and training schools, but detailed descriptions are given of the efforts made in particular towns and districts. In Frankfort, Charlottenburg, Munich, Saarbrüchen, Berlin, and several large towns of Würtemburg arrangements have been made for giving technical instruction in various branches. At Saarbrüchen, in addition to workshops in the hospitals, outside establishments have been set up. A trussmaker has placed a large and well-fitted workshop at the disposal of the disabled, in which the use of machinery, tools, and apparatus can be learned and practised. The owner of the business himself directs the work, and shows men how to construct for themselves suitable artificial limbs and tools.

Of the Würtemburg towns, the largest hospital school is that at Stuttgart, in which instruction is given to wounded as well as disabled soldiers; there were in November last about 5000 pupils in this school, 60 per cent. of these were still in hospital, 30 per cent. had returned to barracks but still attended classes, while 10 per cent. had been discharged from the army, but remained under training.

At the Electric Accumulator Factory in Oberschöneweide, near Berlin, disabled men who have worked in wood and metal trades are given an opportunity, while still under hospital treatment, of regaining efficiency in their former branch of industry. The disabled work with sound workmen, but the nature and extent of their work vary according to their physical capacity as appraised by the medical supervisor. This arrangement is said to have achieved excellent results.

Agricultural training of disabled men has not been overlooked in Germany. Bavaria started an agricultural training school at Landsberg am Lech in the autumn of 1915; since which time 250 or 300 war invalids at a time have been under instruction. The Prussian Government has emphasized in every ministerial circular the importance of providing training in agricultural work for disabled men. Schools for this kind of training have been established in various parts of Germany and Prussia. Many plans have been formulated with

the view of settling disabled soldiers on the land.

The advice is given that disabled men should return as far as possible to work they did before the war; where this is impossible they should be given some other work upon which they can be employed with safety to themselves and their fellow workers.

Considerable progress appears to have been made in employing war blinded men in munition factories. About 50 per cent. of the men blinded in the war are now said to be employed in this way in Spandau, Dresden, Danzig, Cassel, Nuremberg, Düsseldorf, Erfurt, Munich, and other towns.

Disabled officers who have been obliged to leave the army receive from the State (a) a pension corresponding to their peace time income; (b) a war supplement of 720 to 1,200 marks, and in certain circumstances (loss of limb, etc.) a disablement allowance of 900 marks. In addition, a number of public appointments are reserved for them, on State Railways, in the Excise Service, in the Postal Service, Governorships of Prisons, and as Taxing, Stamp Duty, and Death Duty officials. Salaries in these posts vary from 1,800 to 4,500 marks a year.

Bone Grafting.—In the *British Journal for Surgery* for November, 1917, Mr. Ernest W. Hey Groves gives a description of old and new methods of transplantation of bone in the repair of defects caused by injury or disease. The following is a summary of the results of experiments in this direction carried out by himself: (1) The most ideal graft is a piece of living bone used in its entire thickness. (2) Any kind of bone-graft gives better results when used whole than when broken up into small fragments. (3) Fragments of living bone, unless closely in contact with vascular tissue, act as indolent and passive structures, and display no osteogenesis. (4) Dust formed from the living bone does not maintain its vitality. (5) Cortical grafts are far better than intramedullary. (6) An intramedullary graft, if small and loose, takes no part in repair, neither does it act as a splint. If it fits the narrow cavities of the fragments tightly, it hinders osteogenesis and is frequently subject to fracture. (7) The success of a living graft depends very largely upon: (*a*) The extent of its contact with living bone; (*b*) The accuracy of its apposition; (*c*) The firmness of its fixation. (8) Firmness of fixation is of paramount importance in the repair of defects in long bones by grafting. (9) A graft of dead bone (boiled) properly fixed by metal sutures, will give a better result than a living autogenous graft fixed by catgut alone. (10) Metal sutures and pins are useful in the fixation of many grafts. When properly applied they secure the necessary fixation, and there is no evidence that they hinder osteogenesis. (11) For use as pegs or nails there is no advantage in using living over dead bone. (12) Domogenous grafts under favorable circumstances, act just as well as autogenous. (13) Dead bone-grafts are certainly inferior to living when used to fill defects in the long bones, but under favorable circumstances they become strongly incorporated into the living skeleton. (14) Provided that secure fixation of the graft in its bed is not disturbed, mobility of the limb favors osteogenesis, whilst immobilization hinders it.

Gunshot Wounds of the Chest.—A good deal has been written since the outset of the war on gunshot wounds of the chest. It seems to have been demonstrated clearly enough that the mortality, on the whole, from such wounds has not been large. It is true that French medical publications attribute to gunshot wounds of the chest a considerably higher death rate than the records of British surgeons show. However, the higher death rate among French soldiers from this cause is probably largely due to the tendency of French surgeons to operative, while British surgeons pursue more conservative methods. Colonel R. D. Rudolf, writing in the *Lancet*, Nov. 16, 1917, on the subject, concludes as follows: (1) Evidence is lacking that small fragments of shell and shrapnel and likewise rifle bullets and shrapnel balls retained in the lung commonly give rise to any serious trouble. (2) The mortality of gunshot wounds of the chest in patients that have survived the early days of their invalidism and been sent to England with retained missiles in the chest is practically nil if these bodies be left alone. (3) Hence, when it has not been considered necessary by the surgeons at the front to operate immediately, it should not later on be done, unless, indeed, some very definite indication, such as an abscess, exists.

Moving Pictures for the Army Medical Museum.—An important educational innovation, just announced, is the establishment of a new subdivision of the surgeon general's office in conjunction with the Library and Army Medical Museum, to furnish moving pictures or slides of camp activities relating to the conduct of work in the medical department. A suitable repository will be established for the accommodation of positives or negatives of all important military-medical films or slides, which are to be available for instruction purposes, to supplement the courses given under the direction of the medical department in officers' training camps, as well as in the National Guard and National Army camps. They will also be loaned to medical schools for use in lectures and other courses of study. As it has been repeatedly demonstrated that students attain a much higher percentage where courses are supplemented pictorially, this innovation will be appreciated as of immense value. The surgeon general's office seeks the cooperation of the medical profession in securing access to negatives of unusual cases in every branch of surgery not now possessed by the library of moving pictures of the surgeon general's office, and would appreciate the donation of positives where possible. The new branch is under the direction of Col. William O. Owens, curator of the Surgeon General's Library and Army Medical Museum, Seventh and B Streets, S. W., Washington, D. C., to whom correspondence may be addressed.

Health Conditions in National Guard and National Army Camps.—According to the *Official Bulletin* of December 6, the sick rates of the National Guard have improved during the week in some divisions, have remained practically unchanged in others, have slightly increased in the Forty-first, Twenty-eighth, Thirty-fifth, Thirty-eighth, and have considerably increased in the Twenty-seventh Division. Conditions in the National Army have, on the whole, improved during the week. In only two divisions was there an increase in the number of cases of measles re-

ported over that of the preceding week. Reports from all the divisions in which pneumonia has been prevalent show a decrease in the number of new cases, with the exception of the Thirty-sixth Division; the number of cases of pneumonia reported from this division was 454, as compared with 1038 for the preceding week. The total number of deaths in the National Guard for the week ending November 30 was 164, of which 143 were due to pneumonia; the total number of deaths for the preceding week was 171. The total strength of the National Guard is 374,762. The total number of deaths in the National Army for the week ending November 30 was 79, 39 of which were due to pneumonia. The total deaths for the preceding week numbered 60. The strength of the National Army is 426,310.

Surgeon General Appeals for Nurses.—Surgeon-General Gorgas has sent out an appeal to the superintendents of training schools for nurses, to the presidents of alumnæ associations of the same schools, and to the presidents of the State nurses' associations, and State examining boards for registered nurses. The appeal states that the need for nurses is growing daily and to meet it it will be necessary for the Surgeon General's Office to have on file the names of thousands of nurses who can respond to a call on short notice. It is estimated that at least 20,000 nurses will be required in the army hospitals at home and abroad in case the war continues, therefore the applications of all graduate nurses who are professionally, physically, and morally qualified will be given consideration. Nurses will be appointed for three years, if they so desire, or else for the period of the emergency.

Another Medical General.—Our own General Leonard Wood is not the only army commander who began his life work as a physician. General Boriani, who for six weeks has led the brave Italian troops on the Asiago plateau, which, outgunned and outnumbered, have successfully resisted this modern irruption of the northern barbarians, was educated as a physician, and for many years successfully practised gynecology.

Doctors Give Free Treatment to Soldiers' Families.—The American Medical Military Aid Association announces its intention to enlist at least 2000 physicians in New York for the care of the families of soldiers in their neighborhoods. The volunteer physicians are asked to give at least one hour a day to this work and to give it in the same spirit in which the soldiers have volunteered. In order to help defray the expenses of the association an entertainment, which will include an inter-city fencing competition, will be given at the Ritz-Carlton Hotel on December 18. Dr. Ramon Guiteras is president of this organization. Those wishing to volunteer their services are requested to address Dr. John Ernest Gignoux, 616 Madison Avenue, New York.

New York Leads in War Work.—This city has contributed more physicians, surgeons, and Red Cross nurses for service in France than any other American city. It has at present four base hospital units—Roosevelt, New York, Post-Graduate, and Presbyterian—serving "Somewhere in France." The Kings County Base Hospital Unit, No. 37, has been ordered by Surgeon General Gorgas to active service in France soon after the first of the year. When the New York base hospital units now prepared are actually in service the city will have given more than 200 physicians and surgeons and more than 500 nurses as its quota.

Poets' Committee Continues to Send Ambulances.—The Poets' Ambulance Fund reports that it has purchased one hundred ambulances for service in Italy and that seventy-six of these are already in commission. The committee has thus far cabled to Italy over $141,000 for the purchase of ambulances.

Army Needs Surgical Instrument Repairers.—The Medical Department of the United States Army has issued a call for ten men for overseas duty as surgical instrument repairers. Applications from men willing to enlist may be made to Colonel Frederick M. Hartsock, at No. 628 Greenwich Street, New York.

Ex-President Taft Urges Exemption of Medical Students.—At the annual convention of the American Society of Mechanical Engineers, recently held in New York, ex-President William Howard Taft made an address in which he urged that Congress be warned of the danger of making the same mistake that England had made in sending her doctors and engineers into the trenches. He expressed the opinion that Congress had been very remiss in acting in this matter and that it should require these two classes of men to complete their professional training so that they would be fitted for special duty whenever they might be needed.

Estate Offered for Hospital.—The heirs of the large country estate of the late Grant B. Schley have offered this property, comprising 5000 acres of land, to the Government to be used as a convalescent hospital for American soldiers. They have filed a complete description of the estate and of the house, together with its equipment, with the Government.

Large Gifts to Relief Work.—William K. Vanderbilt has contributed $200,000 to relief work among the Italian wounded and needy through Major G. M. P. Murphy, head of the American Red Cross Commission to Europe. The Rockefeller Foundation has made a contribution of $100,000 to the Jewish War Relief Fund which brings that fund up to about $2,150,000.

Business Men Enter Red Cross Service.—In response to a request from Major Murphy, ten more American business men have volunteered for American Red Cross service in France. They will serve without pay and pay their own expenses in connection with their work. They are Mark S. Willing, Chicago; William Prescott Walcott, Readville, Mass.; Credo Harris and Attila Cox, Jr., Louisville; S. A. Barden, Kenosha, Wis.; Louis A. Davis, Philadelphia; John P. Carey, Colorado Springs; Jacob France and Stuart Oliver, Baltimore, and James Mori, Burlington, Iowa.

Salvation Army Plans Work Among Soldiers.—The Salvation Army recently held a meeting at its headquarters in New York City at which plans were outlined for raising a fund of $1,000,000 for work among American soldiers in France. Each State will be asked to raise its proper quota of this fund.

New York, December 15, 1917.

OUR PRESENT KNOWLEDGE OF WEIL'S DISEASE.

INFECTIOUS jaundice, or Weil's disease as it is more commonly called, has recently been the subject of considerable interest and study owing to its existence among the troops in Europe, and more particularly on account of the information which we now possess in regard to the etiology and probable means of dissemination. In 1914 two Japanese physicians, Inada and Ito, discovered the cause of the infection in the form of a spirochete circulating in the blood. It was not until March, 1916, that the first report of their work was recorded in English in the *Journal of Experimental Medicine*. Since this paper was published, several others have appeared which corroborate the work of the Japanese investigators in practically every essential detail. The disease has prevailed epidemically in Japan for a number of years, resulting in a mortality as high as 38 per cent. Epidemics have occurred in the United States and Europe at various times during the past 100 years, but in these countries the disease has been much milder in type than in the Far East. Inada and Ito were led to the discovery of the cause from the fact that they were able to infect guinea-pigs by intraperitoneal injections of blood taken from patients acutely ill in the early stage of the disease. Subsequently they demonstrated the spirochete in stained spreads of the blood. They adopted the binomial nomenclature of *Spirochæta icterohæmorrhagia* for the organism, so that in accordance with the tendency of the times to label diseases biologically when possible to do so, the malady is now alluded to in the literature as spirochætosis icterohæmorrhagica. This designation, albeit somewhat unwieldy, gives expression to two of the most important objective symptoms of the infection, viz., icterus and hemorrhages. The spirochete is of inconstant shape and has no fixed undulations. The thickness is about that of *Spirochæta pallida* or slightly less, and the length varies considerably, being about the length of *Sp. pallida*, showing twelve or fourteen turns. The organism has been cultivated outside of the animal body.

Clinically, three stages of the disease are recognized, viz., the first or febrile stage, the second or icteric stage, and the third or convalescent stage. The incubation period is from six to eight days. The onset in typical cases is usually sudden, with chills and fever, headache, vomiting, muscular pains, congestion of the bulbar conjunctivæ, and albuminuria. The first stage lasts about one week and is followed by jaundice, hemorrhages from the mucous membranes, petechiæ, nervous symptoms, marked prostration, and cardiac weakness. This stage also lasts approximately a week and is the period of greatest mortality. The final stage is characterized by a gradual disappearance of the jaundice, progressive emaciation, and occasionally by the recurrence of fever, remittent in type, and called by the Japanese "after fever." This stage may last from four to twenty days or even longer. The spirochetes are found in the blood in the first stage and toward the fifth or sixth day they begin to appear in the urine. During the second stage the spirochetes disappear from the blood and are found abundantly in the urine, where they can be demonstrated by the India ink method. They continue to be excreted by the kidneys throughout the third stage. Histologically the spirochetes exhibit a wide distribution, being present in most of the organs and tissues, particularly in the liver and kidneys. Fortunately the majority of cases which have occurred among the troops in the present conflict are of a milder form than detailed above. The mortality to date has been comparatively low, probably not exceeding 6 per cent. Cases have been reported with very little or no jaundice, a point of some importance when approaching the diagnosis.

As regards the route of infection, most students of the disease are inclined to the belief that it occurs through the alimentary tract, with also the possibility of infection through the skin. This latter route is suggested by the high incidence of the infection in the coal miners of Japan who go barefoot. That the spirochete is carried by rats is now an established fact. Noguchi found the spirochete in rats in New York City. In Europe and Japan a fairly large percentage of the rats harbor the organism. Rosenau is of the opinion that the disease was originally epizootic among certain rodents, especially wild rats, and after a long sojourn in this species of host its virulence for these animals has been reduced to such an extent as to cause the latter no inconvenience, or at least a state of tolerance for the spirochete has developed. Therefore Weil's disease is probably a primary infection in rats and secondarily transmitted to man. It seems reasonable to assume that the Japanese strain has acquired a marked increase in virulence owing probably to a more frequent passage from man to man. It is believed that the infection is seldom transmitted by the bite of a rat. The rat, like man, excretes the spirochetes in the urine and by this means the soil becomes contaminated with the organism. It has been shown that moist soil is particularly favorable to the proliferation of the spirochetes. Hence measures for the destruction of rats

in camps and trenches are of the utmost importance in the prophylaxis of the disease.

Treatment is largely symptomatic. The Japanese have developed a serum made by immunizing horses. It is administered subcutaneously and intravenously. They report that the ultimate results of the serum treatment on symptoms and final outcome have still to be determined. The serum does seem to cause a decrease in the number of spirochetes in the blood. If the serum is to be of any benefit it should be given early in the disease. Whether serum therapy or some form of chemotherapy will be the most effectual means of combating the infection is a subject for further investigation. The pathogenesis of the "after fever" is another point requiring elucidation.

POSOLOGY AND MODE OF ADMINISTRATION OF ADRENAL EXTRACT.

THE therapeutic indications for suprarenal medication are as numerous as varied. Like thyroid substance, the extracts have substitutive and dynamogenic properties. One may do great things with adrenal extract if he knows how to handle it and is familiar with its indications and contraindications. Practitioners at present seem to know only the theories of adrenal activity. At least this is the opinion of Sergent in the *Journal de médecine et de chirurgie pratiques* for October 10, who adds that they follow a false set of rules in the exhibition of suprarenal preparations. There is too great a fear of large doses, and this is responsible for many failures, for the small dose has a transitory effect. To obtain the desired action it is necessary to give good-sized doses, but they must be given in fractions. The result will be that the patient comes under the influence of the drug, and a sort of equilibrium is maintained. We should reckon always in daily doses in order to get an optimum therapeutic effect.

The case is cited of an attempted suicide in which a drug clerk swallowed 20 c.c. of a 1 to 1000 solution of adrenalin hydrochlorate. A quarter hour later, nothing having transpired, he took 15 c.c. more. Not until after two hours did he develop severe headache, stiff neck, and nose bleed. He decided to live, and at the hospital was bled 75 c.c. by reason of the high blood pressure (no attempt was made to register it). After the venesection he received emetics and inhalations of nitrite of amyl. Still able to walk, he went to bed and waked in his usual health, save that he showed some bloody expectoration. The would-be suicide was tuberculous. Another case showed analogous behavior, and it does not seem likely that any amount of the drug would prove a violent poison, for the very good reason that the greater the dose the greater the degree of vasoconstriction from the local action of the drug on the mucosa. As this condition wears off absorption slowly sets in. The rhinologist knows this fact, and is not afraid of unlimited local application of the drug.

Like numerous other clinicians, Sergent administers the drug *per os*. Thus given, the doses seem to vary much according to the practitioner, but are always relatively small. No account is taken of the fact that adrenal extract is rapidly attacked by the digestive juices. Sergent, however, after a good deal of experience, decided that a special hypodermic method could be devised to replace exhibition by the mouth. The instability of the drug in the stomach, along with its power of preventing its own absorption, seemed to subvert entirely any prospect of a successful use of the mouth. In the hypodermic use there is also vasoconstriction, but it only slightly delays absorption.

What has been said thus far does not apply to the steady use of suprarenal substance in suprarenal insufficiency, which is a different therapeutic proposition. But these patients often suffer from persistent vomiting or gastric intolerance, and then only the hypodermic route will serve. This is necessarily the case in "acute suprarenal insufficiency," as it is seen in the course of acute infectious diseases. It is precisely in acute insufficiency that a large hypodermic dose is indicated. Here the author gives six, and at times as high as eight, milligrams of pure drug in 24 hours. In ordinary internal exhibition, suprarenal extract is usually associated with some other endocrinic principle in capsules, and the author has combined buccal with hypodermic medication in certain cases. When we consider that adrenal extract may be a synergist in the treatment of many maladies it becomes apparent that it demands intensive study.

PREMEDICAL TRAINING IN CHEMISTRY.

THE importance of a fair knowledge of chemistry to the medical practitioner is too patent to require much elaboration. In fact, a comprehensive and accurate knowledge of the chemistry of the human body is of the greatest service to practising physicians. Now, without preliminary preparation in this science, that is, a study of the elements of the chemistry of the human body before the student enters upon his medical curriculum, the student is considerably hampered. He must have the foundation laid before he begins the professional courses. After he has begun, he will not have the opportunity to master the outlines of the chemistry of the body.

Dr. Frederick S. Hammett, of the Harvard Medical School, read before the Fifty-fifth Annual Meeting of the American Chemical Society in September last a paper (published in the *Journal of Industrial and Engineering Chemistry*) in which he dwelt upon the necessity for medical students to know something of the chemistry of the body before they commenced their medical studies, and emphasized the importance of the possession of such knowledge. Nowadays it is well known that the science is fundamental to a rational understanding of the mechanism of the human body. It is claimed that

many diseases have a chemical origin, or, at least, that chemical processes play a vital rôle in the maintenance of health. Thus it is manifestly essential that a physician cannot treat a patient in the most effective manner unless he is able to apply a knowledge of chemical basic principles to the body reactions.

It is plain then that the boy who intends to enter the medical profession should acquire and assimilate a certain amount of chemical knowledge. As Hammett points out, this premedical training in chemistry is essentially a question of what instead of how much. It would be futile to waste the time of the premedical student in learning chemistry which could not be applied to the treatment of the diseases and affections of man. The part of the science of which he should learn the elements during his premedical student days is that which deals with the chemistry of the human body. But of course he should gain a thorough acquaintance with the fundamental principles common to all chemical reaction, and should obtain a broad view of these fundamental principles, rather than spend his time on unessential details. The elements of biological chemistry are not difficult to acquire at school but are very difficult and often impossible to acquire after entrance into a medical school.

Seeing that a knowledge of biological chemistry is essential to the thoroughly efficient practice of medicine, it might seem to be advisable for the medical schools to insist upon preliminary requirements as regards the chemistry of the body. If this were done, the schools and colleges would be compelled to teach the fundamental principles of biological chemistry to those of their students whose intention it was to become practitioners of medicine.

INHUMAN TREATMENT OF FRENCH PRISONERS BY GERMAN PHYSICIANS.

Dr. Christmas recently published a work on this subject, to which Professor Letulle has contributed a preface, a notice of the publication appearing in the Bulletin of *Le Progrès Médical* for October 13. Information was obtained from prisoners exchanged in Switzerland as no longer able to make war. The author is a neutral Danish physician who was asked to carry on the investigation by the French Minister of Foreign Affairs, and his work was done in Switzerland. By a strange coincidence he died suddenly on the day in which his accusing document was presented to the world. He began his undertaking with the conviction that the prevalent beliefs about the ill treatment of the men were gross exaggerations. Imbued with the traditions of German university life, such conduct had been to him simply inconceivable. He was unable to grasp the idea that German sanitarians, with their *esprit de corps*, could have fled from the typhus infested prison camps. It was even said that they had made no effort to rid the prisoners and their belongings of vermin, and thus prevent the epidemics which occurred in at least three camps. Could they have contrived this spread of disease? They at least made no effort to isolate the Russians who had already suffered from it. The result was thousands of deaths among the prisoners and the flight of the German doctors. Some one saw to it that nourishment was not withheld—it was passed in through wickets; but all credit for medical service was due to the French and Russian physician prisoners. The German medical staff eventually realized that the principles of humanity had been violated, and the omission was in part repaired. To-day, in the prison camps, all prisoners are disinfected on admission, and there have been no epidemics of typhus for more than two years. The breakdown in the German sanitary service occurred in January, 1915, and can absolutely not be excused on account of unsettled conditions.

The other subject for discussion cited in the review is tuberculosis. The prisoners, in a condition which attracted infection, and with numerous infections already established, received no more hygienic ministrations than the first group. There were no cuspidors, no separate laundries, no isolation for the already infected. Many men already in the incipient stages were made to work in the mines and factories. In Letulle's opinion it was only too evident that when peace came thousands on thousands of germ carriers would be sent home to France with the attest that they had been "able to work." If such mass infection was deliberately planned or fostered, there was no necessity for deliberate inoculation, as has been charged, for the German authorities knew their method was equally efficacious, and less troublesome for them.

The Prognostic and Symptomatic Value of "Marbled Nails."

Knowledge of the petty symptoms of disease is not now cultivated with the acumen of prescientific days. What practitioner nowadays gives any heed to leuconychia—the white spots on the nails? These details are abandoned to the laity and the pseudologists. Sabouraud, however, insists (*La Presse Médicale*, Sept. 27) that these white spots have both diagnostic and prognostic value. He has often seen them in the following associations: pretuberculosis in the young, neurasthenia of the phobic type, and chronic alopecia—all in the male sex. In females they are much more common than in males, and appear to occur by preference in neurasthenics; for example, in young girls who are mentally depressed and who talk much of suicide and have one or another phobia, such as the presence of down on the upper lip which they fancy makes them repulsive to others. Or perhaps their fear that their hair or eyebrows are falling out. These attitudes are the cause or result of mental depression. Leuconychia is common among young women with skin diseases of various kinds independent of site. It is not believed to be due to the toxin of tuberculosis when seen in candidates for consumption, but to inferior nutrition; for it is equally encountered in hereditary syphilis. The woman who is always tired without

sufficient cause is very apt to exhibit these spots. Sabouraud has seen them excessively developed in simple goiter and Graves' disease. As stated before there is some connection between them and alopecia of long duration and this form may be associated with other anomalies of the nails. To sum up, Sabouraud believes it is a bad symptom, but not a grave one. It does not foretell death, but it is never seen in a healthy subject. We see it in arterial hypotension and mental depression. It is never present by mere chance and whenever present is a sort of vague menace of poor mental or physical health.

News of the Week.

New York Academy of Medicine Remits Dues of Members in Service.—At a stated meeting of the New York Academy of Medicine, held on December 6, amendments to the constitution and by-laws were adopted which provided that the number of Fellows residing in the Greater City of New York and paying dues should be limited to thirteen (instead of twelve) hundred, and the number not residing in the city and paying dues to two hundred and fifty. Another amendment empowered the Academy during the continuance of the war to remit, wholly or in part, or permit the postponement of the payment of the dues of any Fellow while in active service, or to transfer such Fellows from resident to non-resident membership. The annual election was also held this evening. The term of the president, Dr. Walter B. James, does not expire until January 1, 1919. The officers elected were: *Vice-President,* Dr. John Hartwell; *Corresponding Secretary,* Dr. D. Bryson Delavan; *Treasurer,* Dr. Seth M. Milliken; *Trustee,* Dr. L. Emmett Holt; *Member of Committee on Admission,* Dr. Godfrey R. Pisek; *Member of Committee on Library,* Dr. Herbert S. Carter.

Dr. Charles W. Stiles of the United States Public Health Service has been given jurisdiction over sanitary affairs in the zone about Camp Hancock, near Augusta, Ga., and will work in cooperation with the health forces already in operation there.

Pneumonia Slightly on Decrease in New York.—The records of the Department of Health from December 1 to 8 show a decrease in the number of deaths from pneumonia as compared with the previous week, there being 220 deaths from this cause reported, as against 251 for the preceding week.

New York Hospitals in Need of Funds.—Figures from forty-six of the principal hospitals of New York show an average increase in expenses since the United States entered the war of at least 40 per cent. The hospitals find the cost of maintenance greatly augmented by the increase in the cost of surgical dressings and drugs. It is stated that the cost of gauze has increased 450 per cent., and that of atropine and some other drugs has increased 1000 per cent. Private hospitals which accept "city" patients have increased their per capita allowance from ten to twenty-five cents per day. According to the figures compiled by the New York Hospital, ward patients cost $2.88 per day, which is an increase of from 32 to 38 per cent. per capita. The situation is doubly serious for the hospitals, inasmuch as want and worry, due to the absence of the bread winner and the high cost of the necessities of life, have greatly increased the demands made on the hospitals. The Babies' Welfare Association of New York City also issues an urgent appeal for financial aid. This organization acts as a clearing house of 130 charitable institutions in the city, and has provided means of caring for 12,000 babies this year, an increase of one-third over any previous year in its history. The probability, in view of the conditions imposed upon the poor by the war, is that the demands made on the association will be greater in the future than in the past.

Red Cross Relief for Halifax.—On receipt of news of the Halifax disaster the American Red Cross immediately sent out from its headquarters in Washington one hundred physicians and surgeons and one hundred and fifty nurses, as well as other helpers. A second contingent was sent from New England, which included ninety-four physicians and surgeons and one hundred and nineteen nurses. St. Luke's, Mount Sinai, and Bellevue hospitals of New York have volunteered to send units, but as the need for physicians and nurses seems to be provided for, their services have not been accepted.

Charitable Bequests.—The Post-Graduate Hospital, New York, has received a bequest of $5,000 to endow a bed in the children's ward, under the will of Cora V. R. Catlin.

The Alumni Association of Jefferson Medical College is the recipient of a residuary bequest of $10,000 by the will of Dr. Joseph Mark Malatesta of Philadelphia, as a memorial to his widow and his mother. His medical library is bequeathed to the Atlantic City Medical Library.

The Clinical Association of American Peroral Endoscopists was organized in Philadelphia on November 1. The purpose of this new society is, as stated in its constitution, "The study of diseases and accidents occurring in the respiratory and upper digestive tracts, of borderline conditions and their treatment, medical and surgical, by direct inspection." The object of the association is also to impress on the internist and general practitioner the value of bronchoscopy and esophagoscopy as diagnostic methods of precision, and so to make possible the accurate ocular study, in the living subject, of pathological conditions of the esophagus and lungs. The association has elected the following officers: *President,* Dr. Chevalier Jackson of Philadelphia; *Vice-President,* Dr. Hubert Arrowsmith of Brooklyn; *Secretary-Treasurer,* Dr. Henry L. Lynah of New York; *Members of the Executive Committee,* Dr. Wolff Freudenthal of New York and Dr. Samuel Iglauer of Cincinnati.

Sweden Reports Low Death Rate.—According to the Swedish government reports recently received in this country, the health of that nation is better than ever before. The Stockholm death rate has fallen to 12.6 per 1,000 population, as against an average of 15.7. The statistics furnish additional evidence that a considerable restriction in the food supply is beneficial rather than detrimental to health.

Clinics for the Treatment of Syphilis.—In compliance with a resolution recently adopted by the Morris County Medical Society that "if possible, at least three hospitals in the county establish a clinic for the treatment of syphilis or specific blood

disorders," the board of managers of the New Jersey State Hospital at Morris Plains, at its recent annual meeting, authorized the establishment of such a clinic at this hospital. Through the liberality of certain drug concerns the necessary drugs are to be provided without expense to the hospital or State. Prior to this there has been no way by which those unable to pay could receive such necessary treatment.

Dr. Eugene H. Porter, formerly New York State Commissioner of Health, has been nominated Commissioner of Foods and Markets to succeed Mr. John Dillon.

Regulation of Dispensary Treatment of Tuberculosis.—The New York City Department of Health has adopted an amendment to the sanitary code which provides that "no public dispensary where communicable diseases are treated or diagnosed shall be conducted otherwise than in accordance with the regulations adopted, which are to take effect at once." These regulations require that examination and treatment of persons affected with tuberculosis shall be conducted in a special dispensary or department maintained solely for such purpose; that every dispensary be provided with adequate facilities for making microscopic examinations of sputum; that the number of patients examined by one physician shall not exceed five per hour; that every dispensary shall be open at least one day each week for the reception and proper care of patients, and the necessary medical and nursing staff shall be on duty on all the days set apart for the reception of patients; that an adequate follow-up system be maintained; that circulars of instruction and advice be furnished patient; that every dispensary shall examine, and, if necessary, treat at the time of their first visit, all applicants, irrespective of their place of residence; that a complete and adequate record be kept of every case, and that such records shall not be open to inspection by the public or to any person other than the representatives of the Department of Health and such persons as may be authorized by law to inspect such records; that every dispensary in which persons are treated for tuberculosis shall be provided with and employ proper facilities for the examination and treatment of the nose and throat of such patients.

New Tuberculosis Day Camp Opened.—The Boat Committee of the Society for the Prevention and Relief of Tuberculosis formally opened a new day camp, "Manhattan," at the foot of East Ninetieth Street on December 6. Addresses were made by Dr. Haven Emerson, Dr. Herman Biggs, and Dr. Louis I. Harris.

Obituary Notes.—Dr. ANSEEL MCKINSTRY WHITBECK, a retired physician, formerly of Albany, N. Y., and at one time examining physician for the United States Army, died at the home of his daughter, in Brooklyn, on December 5, aged 81 years.

Dr. JOHN H. SLOAN of Santa Fe, N. M., a graduate of the Cincinnati College of Medicine and Surgery, died suddenly in Kansas City, on November 15, aged 65 years. He was several times Mayor of Santa Fe.

Dr. OLAF T. MELDE of Spokane, Wash., a graduate of the Physico-Medical College of Indiana in 1890, died in the Chicago Eye and Ear Hospital on November 16, aged 48 years.

Dr. JAMES MILLS of Janesville, Wis., a graduate of the Northwestern University Medical College, Chicago, in 1883, died on November 18, aged 65 years.

Dr. IRA H. GOSE of Eureka, Utah, died of injuries sustained in an automobile accident on November 12, at the age of 46 years. He was a graduate of the College of Physicians and Surgeons, Baltimore, in 1896, and formerly practiced in Danville, Va.

Dr. JACOB CULLEN BARR, retired, formerly of Lawrenceville, Ill., one of the oldest graduates of the University of Cincinnati, and a former surgeon of the First Ohio Infantry, died at Keokuk, Iowa, on November 14.

Dr. WILL ALDER SMITH of Galena, Ill., died on November 17, 1917, aged 45 years. He was a graduate of Northwestern Medical University, Chicago, in the class of 1897.

Dr. MARY E. BALDWIN of Newport, R. I., died in a Brooklyn hospital on November 21, aged 70 years. She was a graduate of the New York Infirmary for Women and Children in 1874, State secretary for the committee of public health education among women of the American Medical Association, and was actively interested in many health reform movements.

Dr. JAMES LOUIS BEYEA, a graduate of the Homeopathic Medical College of New York, and a Civil War veteran, died in the Flower Hospital, New York, at the age of 85 years.

Dr. ISRAEL C. JONES died at his home in New York City on December 6, aged 66 years. He was a graduate of the Miami Medical College, Cincinnati, in 1874, and Medical Superintendent of the Home for Incurables, New York, since 1876. He was a member of the New York Academy of Medicine, the County Medical Society, the Bronx Medical Society, and the Hospital Superintendents' Association.

Dr. EDWARD A. AYRES of Branchville, N. J., died of pleuropneumonia in the Franklin Hospital on December 7, aged 62 years. He was a graduate of New York University Medical School in 1880, professor of obstetrics in the New York Polyclinic Medical School for twenty years, and the founder of the Mothers' and Babies' Hospital, New York. Dr. Ayres was the author of "The Mosquito as a Sanitary Problem," which won the Carpenter prize at the New York Academy of Medicine, and was published in M. G. Fulton's "Expository Writing" as one of the fifteen best examples of the English language.

Dr. JOSEPH MARK MALATESTA of Philadelphia, a graduate of Jefferson Medical College in 1886, died on November 21 at the age of 58 years.

Dr. JOHN JACOB OTT, a graduate of the Medical Department of the University of Pennsylvania in 1874, died at his home in Pleasant Valley, Pa., on November 22, aged 66 years.

Dr. WILLIAM ALEXANDER ARMSTRONG died at his home in Philadelphia on November 22, aged 77 years. He was graduated from the Philadelphia University of Medicine and Surgery in 1861.

Dr. WILLIAM H. KEIM of Philadelphia died on November 23, at the age of 75 years. He was a graduate of the Hahnemann Medical College and Hospital of Pennsylvania in 1871, for twenty-eight years demonstrator of surgery in his alma mater,

one of the founders of St. Luke's Homeopathic Hospital, and at one time president of the Philadelphia Homeopathic Society and of the Pennsylvania State Homeopathic Medical Society.

Dr. ALBERT A. NORRIS died of nephritis at his home in Philadelphia on November 24, aged 64 years. He was a graduate of Hahnemann Medical College and Hospital of Pennsylvania, in 1887, and for nineteen years chief clerk in the United States mint in Philadelphia.

Dr. QUINTUS L. ADAMS, a graduate of Jefferson Medical College, in 1888, died of pneumonia at his home in Philadelphia, on November 27, aged 51 years.

Dr. DANIEL P. GERBERICH of Lebanon, Pa., a graduate of Hahnemann Medical College and Hospital of Pennsylvania, in 1881, died on November 29, aged 62 years. He was a member of the Senate of Pennsylvania.

Dr. EDMUND W. MEISENHELDER died at his home in York, Pa., on December 1, aged 75 years. He was a graduate of Jefferson Medical College in 1868, a member of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. JOHN TAYLOR JONES of Grass Valley, Cal., a graduate of Cooper Medical College, San Francisco, died on November 20, aged 42 years.

Dr. GEORGE A. CAMPBELL, a graduate of the Boston University Medical School, and formerly a practitioner of medicine in Manchester, N. H., died on December 3, aged 60 years.

Dr. WILLIAM GIBSON MCGLUMPHY, a graduate of Starling Medical College, Columbus, Ohio, in 1882, died at his home in Moundsville, W. Va., on November 26, aged 67 years.

Dr. SAMUEL PARKER COTTRELL, formerly of Boston, and at the time of his death a member of the Newport, R. I., Board of Health, died in the latter city on December 3, aged 57 years. He was a graduate of Jefferson Medical College in 1882, and was successively professor of diseases of children in St. Paul's Medical College, assistant surgeon at the Massachusetts Women's Hospital, lecturer at Tufts Medical College, chief surgeon at the Boston Emergency Hospital. He served as surgeon in the army during the Spanish-American War.

Dr. OSCAR M. LEISER of New York died suddenly on November 8, aged 43 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1896, a member of the American Association for the Control of Cancer, the New York Academy of Medicine, the American Medical Association, and the Medical Society of the County of New York. He was an official of the New York City Health Department and a captain in the Medical Reserve Corps of the U. S. Army.

Dr. ROBERT E. CATO of Americus, Ga., a graduate of Jefferson Medical College in 1886, died suddenly of heart disease on November 26.

Dr. EDWARD W. KARRMANN of Cheshire, Conn., a graduate of New York University Medical College, in 1884, was killed in a collision between his automobile and a trolley car on November 28, aged 65 years.

Dr. ALBERT H. STEINBRECHER died of heart disease at his home in Detroit, Mich., on November 25, aged 59 years. He was a graduate of the Detroit Medical College in 1881, professor of medicine in the Detroit Medical College, and physician to St. Mary's Hospital and the Woman's Hospital and Infants' Home, Detroit.

Dr. JAMES WILLIAM KOONTZ, a graduate of the Kentucky School of Medicine, Louisville, in 1894, for many years a practitioner of Greenville, Ky., and surgeon for the Illinois Central Railroad Company, died in Charleston, W. Va., on November 20, aged 47 years.

Dr. ISAAC R. MAJORS, a graduate of the Memphis Hospital Medical College, in 1890, died at his home in Searcy, Ark., on November 24, aged 49 years.

Dr. HORACE B. HILL, formerly assistant superintendent of the Maine Insane Hospital, Augusta, Me., and a graduate of Long Island College Hospital Medical College, in 1880, died on November 22.

Dr. JOSEPH C. DE VARONA of New York City, a graduate of Bellevue Hospital Medical College in 1865, died at the home of his brother in that city on November 30.

Dr. ANDREW TAYLOR STILL, the founder of osteopathy, died at his home in Kirkville, Mo., on December 12. He was born in Lee County, Va., and studied medicine in a Missouri college. He served as surgeon with the Union Army during the Civil War and at its close settled in Kirksville. In 1874 he began the practice of osteopathy and in 1882 founded the first school for instruction in that method.

5. Treatment of Pernicious Anemia—Especially by Transfusion and Splenectomy.—George R. Minot and Roger I. Lee offer the results of their study and work on this condition in stating that there is no known treatment that cures pernicious anemia. From a study of 96 cases and the literature, the treatment of this disease, especially by transfusion and splenectomy, has been considered. Forty of the 96 cases were not transfused or splenectomized. The first essential for treatment is a correct diagnosis. The diagnosis is not to be made on the blood smear alone and, unfortunately, is seldom made early. A careful, detailed study of the activity of the bone marrow and red cell destruction is important for prognosis and therapy. Not only one but all of the three chief elements of the marrow must be studied: the polymorphonuclear neutrophiles, red cells, especially young red cells, and platelets. Observations on the latter are important. Certain elements, often taken to indicate stimulation of the marrow, do not always indicate this, or at least are not always associated with a favorable prognosis. Such elements at times are of bad omen. It has been pointed out that certain types of pernicious anemia are to be recognized. Those types of cases that do the best spontaneously usually, but not always, receive the most benefit from treatment. Older patients are more apt to have a less relapsing and less hemolytic type of the disease than younger individuals. Cases with enlarged spleens, together with somewhat enlarged livers, when these enlargements are associated with and probably due to hemolytic activity, are apt either to have, or to have had, a more favorable course of the disease than those

cases without such enlargements. It is important that all cases should have proper general treatment. Transfusion and splenectomy offer the best means for inducing remissions, though a remission can occur spontaneously as marked as those inaugurated by these procedures. No case is too sick for transfusion. Transfusion can give rapidly symptomatic benefit. It may also, either directly or indirectly, rapidly or slowly, cause stimulation of the marrow or allow increased activity of the marrow, so that a remission is inaugurated. The amount of blood to be transfused has not yet been definitely settled. Their cases usually received about 600 c.c., although they have obtained definite results from 150 and 1500 c.c. In cases with a very low hemoglobin massive transfusions are often necessary; likewise when a transfusion is done to check hemorrhage associated with marked diminution of the platelets an amount sufficient to contain enough platelets to check the hemorrhage is necessary. Transfusions may be employed either repeatedly every 3 to 7 days, or they may be given one to three times some 7 to 14 days apart, with particularly the idea of inducing a stimulation of the marrow. The donor, of course, should be healthy and with a negative Wassermann reaction, and one whose red cells are not agglutinated by the patient's serum, and preferably one whose serum does not agglutinate the patient's cells, so that both donor and patient belong to the same isoagglutination group. Isohemolytic reactions will not occur with properly selected donors. Other reactions of unknown nature, usually much less severe, cannot at present be avoided. It is suggested that some reactions following transfusion may be dependent upon the fact that the patient has previously received transfusions of blood. Such reactions are, perhaps, associated with a rapid and excessive accumulation of blood pigment in the body. Splenectomy for pernicious anemia is a palliative operation. It checks the red cell destruction and increases the activity of the marrow. Good remissions follow splenectomy more consistently and uniformly than after other forms of treatment. Splenectomy is reserved for only selected cases in certain stages of the disease. It is a serious procedure, is not to be urged, but at times may be advised, provided the patient understands that its effect is only temporary. The cases of pernicious anemia that approach the disease hemolytic jaundice are the most suitable ones for splenectomy. By means of transfusion and splenectomy they believe that patients do better and can be made more comfortable while they live, and that in certain instances they may perhaps live longer than without such treatment. Probably when transfusions are begun relatively early, so that the patients never remain very anemic for long periods, the best ultimate results will be seen. Roentgen-ray exposures of the spleen have at present shown no definite beneficial effect.

7. A Prompt Emergency Hypnotic.—C. J. Douglas has for several years used a combination of hyoscine and apomorphine which has proved a desirable emergency hypnotic. There is here a combination of two remedies that are entirely unlike, each attacking the problem from a different angle, each supplying the other's deficiencies, and each correcting the other's faults. When quick action is desired, accompanied by entire safety, Douglas has found this combination most dependable. Also in the treatment of the excited stage of alcoholism and other mental ailments it is especially valuable. The two drugs are mixed and administered hypodermically in the one injection as follows: Hyoscine 0.005 grain, and under no circumstances should 0.01 grain be exceeded, with the average dose as 1/150 grain; apomorphine 0.025 to 0.02 grain is usually sufficient. The synchronous action of these drugs is: In the first hour hyoscine produces delirium, while apomorphine brings on sleep; in the subsequent hours hyoscine produces sleep. Thus, while the action of the apomorphine is more or less transient, it overcomes the delirium produced by hyoscine, the hypnotic effect of which lasts for several hours.

7. Facial Paralysis Following Pasteur Antirabic Treatment: Report of a Case of Facial Diplegia with Onset Seventy-Three Days After the Beginning of Prophylactic Inoculations. Robert L. Levy.

1. Clinical Course and the Diagnosis of Trachoma.—M. H. Foster, Surgeon, U. S. Public Health Service, describes trachoma as a specific, transmissible, destructive inflammation of the conjunctiva, characterized by the formation of the so-called trachoma granulations, which may be either papillary or follicular; the ultimate formation of scar tissue; marked chronicity, and intractability to all forms of local treatment. Clinically it presents itself in two forms: (1) fulminating trachoma, and (2) slow trachoma. The first is characterized by a very acute inflammation, coming on suddenly with usual symptoms of a severe infection of the conjunctiva. This type is rare, "slow trachoma" typifying the ordinary forms of the disease. With reference to the time of cure, Foster states that there is a diversity of opinion. Patients attending clinics are often discharged as cured when acute inflammatory symptoms have subsided and there is no discharge. Such cases, however, almost invariably relapse sooner or later, and the mere cessation of secretion and the acute subjective symptoms should not be taken as proof of recovery from the disease. When an eye has become infected with the trachoma virus it is liable to a recurrence as long as any normal conjunctiva, or any lymphoid tissue in the conjunctiva remains. The infection lingers in the granulations apparently indefinitely, and some trifling local irritation or constitutional disorder may cause it to spring into renewed activity at any time, and thus produce an acute exacerbation of the disease. A case can never be said to be certainly cured until all the conjunctiva of the upper lids has become completely replaced by smooth, white, avascular, fibrous scar tissue, and the lower lids are free from any evidences of the disease. Avascular scar tissue cannot be infected by the virus of trachoma. In treating trachoma with silver nitrate, copper sulphate, grattage, expression, etc., the cicatricial process is simply hastened by chemical and mechanical destruction of the normal and abnormal tissue of the lids and the irritation resulting from these various measures.

1. Bradshaw Lecture on the Causes of Disease.—Ernest S. Reynolds, in his thesis on this subject, delivered before the Royal College of Physicians of London on November 8, 1917, gives as a basis for discussion the definition of disease as that condition of an individual in which there is, apart from normal age changes, a harmful change of the structures, or functions, or sensations usually found in the average man of any particular race. This definition includes neurasthenia and hysteria among diseases, but not malingering. For a definition of cause he turns to Mercier's: "A cause is the action or cessation of action connected with a sequent change or accompanying unchange in the thing acted on." With Mercier he shows the difference between *cause* and *condition* with relation to disease. Conditions such as climate, age, etc., are not primarily causes of disease, but contributing factors, back of which is the real but perhaps unknown cause. In order to simplify the means of reaching true causes he takes as an example a healthy community containing 1,000 healthy men and 1,000 healthy women, each aged 20 years, free to marry, with no hereditary taint, and put to live in a perfectly healthy island with sufficient flora and fauna to maintain life, and not under a fantastic communistic government, and then uses his imagination as to what diseases they would suffer from and from what they would die. Theoretically none of these people would have any disease, and would all die at 100 years of age from the natural processes of age. But since, as physicians, we know that no two human beings are exactly alike in physical and mental processes, and react differently to environment, various affections would occur and ages of death would vary accordingly. He carries his illustration further by including the next two or three generations, without any admixture with the outside world. As a result he finds ten different causes for disease among his inhabitants as follows: Injury, food and feeding bringing on poisoning, poisons, occupation, stress, abnormal metabolism, abnormal age changes, neoplasms, parasites, and heredity. Naturally, the percentage of deaths would be higher from natural changes due to age than is now prevalent in England today. He then allows unrestricted immigration into the island, but finds no new cause of disease, but only an intensification of three of the causes, namely, stress from increased competition, parasites, and heredity. The parasitic affections would especially act as causative agents which are of fixed types, such as syphilis, tubercle, the exanthemata, etc., and he further points out the important factor the parasite is in the production of disease. Heredity, of course, does not explain the cause of a disease; it is only a condition, and some of the other nine classes of causes have to be brought in as factors before an effect is produced. But the importance of heredity in determining the future of a race is so great that it merits a place on this list. He gives eight groups under which hereditary diseases may be placed, among which are direct infection, of which syphilis is the one example; possible results of extrinsic poisoning in the parents by such agents as alcohol or lead; structural changes; altered metabolism such as gout, diabetes, and obesity; tendency to germ infection, illustrated by acute rheumatic fever. Reynolds emphasizes the enormous influence of heredity on this condition, which he considers is of equal importance as regards ultimate human suffering as tuberculosis. Among the groups he also gives nervous irritability or instability, and tendency to abnormal age changes. In order to show the variance in the causations of morbid conditions, he uses the English mortality tables for 1913 (in order to exclude the war), and finds a total of 500,000 deaths. Of these 134,000, or one-fourth, were due to infectious diseases directly, and of this number 50,000 (one-tenth of the whole death rate) were due to tuberculosis in some form, 37,000 to pneumonia, 10,000 to measles, 6,000 to influenza, and 5,000 to whooping cough. Thirty-nine thousand were due to some form of malignant disease, 38,000 to blood-vessel condition, 15,000 to Bright's disease. There were 18,000 premature deaths, while old age was accredited with 30,000 deaths, or one-seventeenth of the whole. While these figures give some hint of disease conditions, they give little of prime causes. For instance, three most important causes have very low figures—venereal diseases 2,000, alcoholism 1,900, and rheumatic fever 1,770. A comparison of his list of causes with this given list leads one to wonder how many of the 38,000 deaths from disease of the blood-vessels were due to abnormal old age or to stress and how many to syphilis, what proportion of the 30,000 ascribed to the digestive system was due to food and feeding, and what proportion of nervous diseases was to be attributed to germs, to abnormal old age, or to heredity. He makes especial mention of disseminated sclerosis, of which he has made particular study for years, and calls attention to one symptom so commonly overlooked, that of the optic nerve. He considers that this disease may be caused by a poison acting on certain special nerve tissues. If it is an intrinsic poison, it may be either a perverted internal secretion or a poison derived from the alimentary canal, possibly as the result of constipation. He offers his grouping of the causes of disease as a convenient one which may be of assistance in reaching the haven of real cause, and then after reaching it the performance of the next highest duty, that of real prevention.

1. The Bradshaw Lecture on Misplaced Organs. John Bland-Sutton.
2. The Microscopic Examination of the Brains of Two Men Dead of Commotio Cerebri (Shell Shock) without Visible External Injury. F. W. Mott.
3. Preliminary Report on the Pathological Findings in Nerves following War Injuries. Sydney M. Cone.
4. Three Cases of Melena Neonatorum Successfully Treated by the Injection of Whole Blood or Blood Serum. Robert Hutchison.

1. The Bradshaw Lecture on Misplaced Organs.—John Bland-Sutton, in this lecture before the Royal College of Surgeons of England, November 8, 1917, refers to the migration of many mammalian organs during embryonic and fetal life and to some of the changes then occurring. There is nothing quite so fascinating, he says, as watching the pulsating embryonic heart of a chick lying clear of the body cavity, then to trace its gradual enclosure, translation, and final imprisonment by the completion of the walls of the body cavity. Occasionally it fails to reach its normal place, and is detained in the neck, an embryonical accident not uncommon in calves. In considering the undescended cecum he states that in a large number of mammals the whole intestinal tract from the middle of the duodenum to the end of the colon is slung on a common mesentery. This is the arrangement found in the human embryo and which occasionally persists in adults, leading to some remarkable displacements of the cecum that cause a very fatal form of intestinal obstruction. In the early embryo the cecum does not exceed in circumference a contiguous coil of ileum, and even at this stage it is defined by the vermiform appendix and lies in contact with the under surface of the liver, gradually enlarging, it descends to the normal position in the right iliac fossa. It is a common condition to find the cecum completely invested with peritoneum, and almost as mobile as a small ovarian cyst. Occasionally the cecum is retained in the fetal position, immediately under the liver. The alarming frequency of septic disease of the vermiform appendix leads surgeons to study carefully variations in the positions of the cecum and anomalies connected with its descent, for these determine the final position of the appendix. Experience in the operating theater has taught these men that the vermiform appendix may lie in any position between the under surface of the liver and the floor of the pelvis. Bland-Sutton, on several occasions, has found its tip touching the gall bladder. When the appendix is retrocecal, it often lies in contact with the kidney. After careful study of the retrocecal appendix, not only on account of the

difficulty that sometimes attends the diagnosis of appendicitis when it lies behind the cecum, but also to ascertain the causes for this unusual position, his explanation for the unusual situation of this organ is that in many cases in which the appendix lies vertically behind the cecum its tip is firmly fixed near the liver. Thus it happens, if the tip of the fetal appendix is anchored, it cannot descend with the cecum into the iliac fossa, but the descending cecum gradually lengthens the appendix. This will explain the fact, familiar to surgeons, that a retrocecal appendix is often abnormally long, straight, and lacks a mesentery. Occasionally Bland-Sutton has found the tip of a retrocecal appendix so firmly fixed to the peritoneum in the loin that the cecum, though it has descended into the iliac fossa, has had its blind end turned upwards to the liver. In such a case the cecum is suspended by the appendix. The mechanism by which the cecum migrates is associated with that determining the descent of the testes and ovaries. Nondescent of the sexual glands is often associated with an undescended cecum, and those ill-understood movements, or readjustments, of the peritoneum that occur at a late period of fetal life. He further states that some of the changes in the position of abdominal viscera are almost romantic. It is not generally appreciated that the kidneys undergo a marked translation during fetal life. He has found a kidney in the hollow of the sacrum in both a man and a woman. In the case of the latter it was mistaken before operation for a distended fallopian tube. When the pelvic organs were exposed in the course of the operation a curious set of anomalies appeared. The uterus was of the unicorn variety, and had a right ovary, tube, and broad ligament, while the right kidney was in normal position. This woman conceived after the operation and was delivered without difficulty, in spite of the other kidney in the hollow of the sacrum. A pelvic kidney may become hydronephrotic, and it has happened that a gynecologist, unaware of this anomaly, removed such an organ under the impression that it was an ovarian cyst. The position of the kidney in the human embryo is influenced by the size of the adrenal. During intrauterine life the adrenals are large and conspicuous. In the first half of the second month the adrenal is double the size of the kidney, and the two organs are widely separated. Then the kidney grows faster than the adrenal, and at the end of the second month they are equal in size, while later the kidney is the more conspicuous organ. The relationship of the kidney to the iliac arteries in the embryo explains the occasional occurrence of a pelvic kidney in, or near, the pelvis. The large size of the adrenal in the human embryo is due to the preponderance of the cortex over the medullary portion, and this in some subtle way is correlated with the development of the cerebrum. The hypertrophy of the adrenal cortex in embryonic life is a feature peculiar to human fetuses, and if the cerebrum fails to develop, as in anencephalous human fetuses, the proportions of cortex and medulla are like those of other animals. As far as can be known pelvic kidneys have not been found in other mammals. This may be used as an additional evidence tht the caudal displacement of the kidney in the human embryo is due to the predominance of the adrenal cortex.

Infundibular Syndrome in a Tumor of the Third Ventricle.—Salmon refers to a case recently described by Claude and Lhermitte of tumor of the third ventricle. In addition to certain other symptoms, there was a special syndrome which comprised tachycardia and arrhythmia, hypersomnia, and polyuria with polydipsia, and which would be termed by many authors a pituitary syndrome. At autopsy the hypophysis was found to be quite normal, but the infundibulum was involved in the growth, and hence the term infundibular syndrome was used in this connection. Numerous arguments are given in justification of this term. The syndrome differs from the hypophysis syndrome in several ways, for in the latter there are no circulatory symptoms—at least no tachycardia and arrhythmia. Nor does disease of the hypophysis proper cause narcoliptic crises which usually are associated with the midbrain. Certain authorities even associate polyuria with the infundibulum. The author takes exception to this conception of the infundibular syndrome, especially as he has already published some work on the hypophysis and sleep. In his monograph on the latter he gives data which accuse the hypophysis as an organ concerned in crises of somnolence. Narcolepsy has disappeared after ablation of the hypophysis, and even after the use of *x*-rays for pituitary growths. Even the internal administration of hypophysis extract has removed narcolepsy. Moreover, hypersomnia accompanies other types of endocrine insufficiency (myxedema, etc.), and disease of the nasopharynx. So-called adenoid hypersomnia has been benefited by hypophysis extract. In brief, what Claude and Lhermitte call the infundibular syndrome agrees with Salmon's hypophysis syndrome so that the two views may be harmonized by a hybrid term—hypophysis-infundibular.

Auscultatory Sphygmomanometry.—Cottet states that while this diagnostic resource was first proposed in 1905 we hear very little of it today. The principle underlying it was discovered by Marey, and consists of the production of a certain noise by the passage of the blood through an artificially compressed artery. This forms an auditive equivalent to the arterial oscillations. In cylindrical compression of a limb by a pneumatic cuff the systolic pressure is gradually overcome so that the artery beyond the region of compression is empty of blood, although maintaining its caliber. When this compression is released the blood rushes into the empty vessel, causing a special pulsation, which disappears when the circulation has been reestablished. At the moment of the "decollapse" of the vessel a special sound should be audible. The variation in the sounds corresponds to the variations recorded by the sphygmomanometer, *i.e.* the diastolic, or fundamental pressure, and the systolic, or special pressure, and serves as a control.

Lo Sperimentale.

October 15, 1917.

Anticholera Vaccination.—Castelli states that in June, 1916, ninety individuals, between 21 and 35 years of age, were vaccinated against cholera—45 with nucleoproteids, and 45 with bacterial vaccines. Neither substance produced any local reaction, and the general reaction was invariably mild, consisting in fever which only exceptionally exceeded 38, occasional headache, and, rarely, diarrhea. Reactions were of more frequent occurrence after bacterial vaccination (37 per cent. after the first and 64 per cent. after the second vaccination); while corresponding figures after vaccination with nucleoproteids were 22 and 24 per cent. In the serum of subjects vaccinated with nucleoproteids there was always absence of agglutinating power, while after vaccination with bacterial vaccines agglutination was present in dilutions varying from 1:25 to 1:250, the latter being higher and more constant in serum taken 30 days after vaccination. All the sera showed a bacteriolytic property, demonstrable in dilutions of from 1:25 to 1:500. Sera after bacterial vaccination acquired a maximum of bacteriolytic power more rapidly (in 30 days, as against 40 days after nucleoproteid vaccination), but nucleoproteid sera were more potent *per se*, and over longer intervals, doubtless because of their want of agglutinative power.

Causes of Camp Icterus.—Zirone and Capone publish the following conclusions: in 200 cases of icterus submitted to study by the authors an infectious factor was present in a large proportion. Only in 18 per cent. were the cases of toxic nature. Examinations of the blood picture failed to show any difference between toxic and infectious types. The great majority showed lymphocytosis with or without mononucleosis. Eosinophilia was often present. Serodiagnostic tests showed positive results for typhoid and paratyphoid in 45 per cent. of subjects who had been vaccinated. In 3 per cent. of all cases the *Spirochæta icterohæmorrhagica* was present. Much care must be taken in the diagnosis of these cases because other spirilla may be pres-

ent in the blood. In urinary tests the spirochete in question was found with a frequency comparable with that for the blood. Injection of spirochetous matter into guinea pigs caused a mild degree of the disease—spirochetic sepsis without icterus, and in some cases no result at all. Wassermann and other complement deviation tests were negative. The authors believe that spirochetosis was more frequently present than was apparent.

Correspondenz-Blatt für Schweizer Aerzte.

October 6, 1917.

Dangers and Treatment of Placenta Previa.—Labhardt gives figures from the Basle clinic for the period 1906-1915 as follows: number of labors, 16,596; cases of placenta previa, 123, with 12 maternal deaths = 10 per cent. Of this number 5 died of hemorrhage, 4 of sepsis, and 3 of air embolism. The relative child mortality was 58.6 per cent. (including prematures and macerated, 62.6 per cent.). The causes of hemorrhage are intimately associated with low insertion of the placenta, where the musculature is thin, and moreover, invaded by chorionic villi. The lower segment of the uterus is naturally dilated by the fetal head to its fullest tolerance. If the placenta is inserted into this segment it is detached during dilatation. Detachment occurs under two different mechanisms, equatorial and meridianal, according to the direction of the muscular bundles. During expulsion the fetus mechanically distends the lower segment, and to this is added retraction in the longitudinal direction, which causes further detachment. The hemorrhage which follows varies directly with the area of surface detached. Similarly the greater the area of insertion the greater the likelihood of early loss of blood. Mere hemorrhage is seldom the cause of death, but the patient is greatly weakened and predisposed to certain accidents. Further hemorrhage may occur during the third stage of labor and afterwards. Normal contraction of the uterus can hardly take place in the insufficient lower segment. This seems to be the greatest source of danger to the patient. Deaths from hemorrhage usually occur during the placental period or shortly after. We have to reckon with the fact that in placenta previa there may occur abnormal adhesiveness of the placenta. The relations of previa to sepsis and air embolism are too well known to require discussion. How may we circumvent all of these dangers or reduce them to a minimum? Diagnosis should be easy and premature separation of the placenta readily excluded. Hemorrhage in the absence of symptoms of this affection means a previa in the vast majority of cases. Therefore patient may usually be spared an internal examination. This also applies to the tamponade. Figures have shown that fever, infection and death occur more frequently in tampon cases. Even the so-called prophylactic tamponade before transport to the clinic should be foregone. So much for guarding against sepsis. In preventing fatal hemorrhage and high fetal mortality the problem is more or less a desperate one. Like his colleagues, the author is sorely tempted to advocate cesarean section to give the child his chance. With fetal mortality zero many children saved would offset an occasional maternal death (the author does not so express himself but this is the real crux of the matter).

Hygiea.

August 31, 1917.

Case of Myeloid Leucemia with Bilateral Growths the Motor Nervous System.—Agduhr selected one-half of the members of four litters of kittens 4 to 6 weeks old and subjected them to training in the form of gradually increased climbing movements. The controls were kept in cages so small that hardly any opportunity was permitted for movements of any sort. The training was kept up for seven months. During the last two months each kitten climbed up a suspended piece of sacking 3 meters long at least 100 times daily. The nervous system was investigated both experimentally and morphologically in both trained animals and controls, and comparisons made between members of the same litters. The results were such as to warrant, in the author's opinion, the following conclusions: (a) Effects of training on growing animals are expressed by hypertrophy of most of the elements of the peripheral nervous system, especially in such regions as are most associated with the apparatus for active movements; (b) relative increase in the number of plurisegmentally innervated muscle fibers; (c) increase in the number of neurites in both dorsal and ventral roots; (d) local enlargement of the medulla spinalis wherever the active motor apparatus was involved in the training—an enlargement which as far as could be determined was due to an increase in the number of conduction paths; (e) increase in the number of root cells; (f) enlargement of the brain in mediolateral direction, nasal from the fissure of Sylvius; (g) at least relative enlargement of the central convolutions with the therewith involved increase in the mediolateral depth of the fissura cruciata; (h) increase in the Betz giant pyramid cells; (i) relative increase of the medullary portion at least at the level of the central convolutions.

Finska Läkaresällskapets Handlinger.

July, 1917.

Histogenesis of the Papilla or the Serous Ovarian Cystoma.—Jännes of Professor Engström's clinic has studied a large number of ovarian cysts of the papillary serous type in order to ascertain whether certain formations discovered by Wichmann in parovarian cysts were present. The entire material was studied macroscopically, and 18 cases chosen for histological examination. Wichmann had discovered the presence of formations which resembled hydatids in the terminal ramifications of the papillæ. The author found this feature in ovarian cysts and was unable to see any evidences of retrograde change. The tissues seemed sound, wtih the exception of edema in the very lax connective tissue. In papillæ with firm connective tissue there was seen at the base active proliferation of both connective tissue and epithelium. But where the stroma was lax with suggestion of adenoma papillæ the proliferation of the connective tissue was more or less inconspicuous in comparison with the rapid growth of epithelium and the abundant vascularization of the subepithelial tissue with dilated, thin-walled blood vessels. In regard to histogenesis the author believes it to be analogous to that described by Wichmann for parovarian cysts. The subepithelial connective tissue layer, rich in nuclei, becomes edematous from whatever cause. With the epithelium it proliferates rapidly, and as a result on elevation the future papilla appears with eventual formation of the hydatiform vesicles. The connective tissue proliferation at the base of the papillae becomes organized.

Pulmonary Consumption in the Workmen of Certain Finnish Towns.—Therman reports on the result of an investigation conducted by him in 1915 into the health of certain workmen examined in an earlier survey. These individuals, employed in a paper mill, were found to have tuberculosis in 1914. The survey extended to the families of the workingmen, and also included suspects. The author discovered new cases of the disease. Both surveys are illustrated by graphics to bring out the progress of the disease, and of the antituberculous propaganda, with special reference, for example, to improved housing.

Case of Myeloid Leukemia with Bilateral Growths in the Orbit Causing Exophthalmus.—Jansson emphasizes the fact that the reported cases of leucemic orbital tumors belong under lymphatic leucemia. He then describes a case of myeloid leucemia in which the same type of growth was present. The patient was a peasant girl of 16, who was at first said to have Graves's disease, with exophthalmus, largely because of normal liver and spleen finds. Sudden increase of exophthalmus, with appearance of cervical lymphnode swellings, and a blood count (myelogenous cells 85 per cent.) made the correct diagnosis. Tumors were palpable behind the projecting eyeballs; they had a cartilaginous feel, and seemed to be adherent to the orbit. The treatment consisted of injections of arsenic, and at first there was marked improvement in the exophthalmus. But this benefit was transitory and death resulted in four months.

Book Reviews.

A Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Third Edition, Completely Revised and Rewritten. Edited by Thomas Lathrop Stedman, A.M., M.D. Complete in Eight Volumes. Volume Eight. Illustrated by Numerous Chromo-lithographs and Three Hundred and Thirty-seven Half Tone and Wood Engravings. Price, $56.00 per set. New York: William Wood & Company, 1917.

Most of those who are fortunate enough to be owners of the new edition of the Reference Handbook have probably awaited the publication of the final volume with a feeling akin to that of one who awaits the completion of a new home. A preliminary examination of its pages reveals at once a wealth of new material. The student of medical history will be attracted by the fascinating exposition of the history of surgery by Stephen Smith, whose life has been contemporaneous with the entire era of modern surgical revolution. The latest word in neurology is typified in the articles on the Sympathetic Nervous System, in which the newly differentiated disorders of the autonomic system are discussed in satisfying detail; and on the Endocrinous Syndromes, in which the uniglandular and pluriglandular syndromes, as recently defined, are completely summarized. The article on Typhus Fever is written in the light of the newer bacteriological studies and the experiences during the present war. One is told that the Serbian epidemic which claimed 135,000 victims, including 30,000 of the 70,000 Austrian prisoners, was brought under control within a period of four months after the various sanitary commissions began their work. Because of its practical importance and because of the fact that this subject is treated in a stepmotherly fashion even in the large treatises on surgery, the article on Ulcers, especially the treatment of leg ulcers, deserves special mention. This article is illustrated by means of a plate showing different types of leg ulcer and various methods of treatment. A full exposition of modern statistical studies of Variation is perceived in the article on this subject, in which it is shown that a knowledge of the biological facts of variation has a practical bearing in medicine and surgery. The biographical sketches forming an interesting part of this volume include those of Sydenham, Franciscus and Jacobus Sylvius, Sir Henry Thompson, Tissot, Trousseau, Valsalva, Van Helmont, Van Swieten, Velpeau, Vesalius, and von Ziemssen.

Among the special articles may be enumerated the following: Suicide; Tattoo Marks; Injuries and Diseases of Tendons; Teratology; Teratoma; Diseases, Injuries, and Anomalies of the Testis and Epididymis; Thalassotherapy; Thirst; Thoracic Surgery; Thymus; Thyroid Gland; Goiter; Tics; Tonsils; Training Schools for Nurses; Transplantation of Tissues; Typhoid Fever; Gastric and Duodenal Ulcers; Diseases and Injuries of the Ureters; Injuries and Diseases of the Urethra; Urine; Diseases of the Cervix Uteri; Displacements of the Uterus; Involution of the Uterus; Malformations of the Uterus; Tumors of the Uterus; Vaccination; Vaccine Therapy; Malformations and Diseases of the Vagina; Physiology of Vision; Vital Statistics; Wassermann Reaction; Water; and Yellow Fever.

In a work of this kind, the publication of which has been comprised within a period of about four years, it is inevitable that there should be an Appendix in which are recorded all the more recent advances in medical science. The Appendix includes articles on the following subjects: Antinarcotic Legislation, Asiatic Cholera, Health Insurance, Anomalies of Muscles, Osteopathy, Paraffin Wound Dressings, Poison Gases in Warfare, Prescription Writing, Protozoa, Social Service, Spectacles, Stethoscope, Trypanosomiasis, Ultramicroscopy, Anomalies of Veins, Pathology of Veins, and Antiseptic Irrigation of Wounds. The last is an ample exposition of the Carrel-Dakin method of wound treatment as evolved during the present war.

The General Index, which comprises a section of 105 pages at the end of this volume, greatly enhances the value of the Reference Handbook. All special articles are referred to by numerals in heavy type. A great many other subjects that are discussed in the text of these special articles may be located in the general index, in which they are referred to by numerals in light type. Apart from its value as a means of quick reference, this index may be used as a guide in systematic courses of reading.

The Medical Record Visiting List, or Physicians' Diary for 1918. Revised. Price, from $1.50 to $4. New York: William Wood and Company.

This well known visiting list still retains its position as the most convenient and handsome of the works of this kind. The present issue has been revised, so that the dosage table conforms to the latest revision of the United States Pharmacopœia. A new table of diagnosis of contagious diseases has been inserted. In addition to the miscellaneous information, there will be found the usual pages for visiting list, consultation practice, obstetric engagements and practice, vaccinations, deaths, addresses of patients and nurses, and cash accounts. The paper is good, and the size and general appearance are attractive. For general convenience it is unsurpassed.

Poliomyelitis, in All Its Aspects. By John Ruhräh, M.D., Professor of Pedriatrics in the University of Maryland Medical School and the College of Physicians and Surgeons, Baltimore, and Erwin E. Mayer, M.D., Instructor of Medicine in the University of Maryland Medical School and College of Physicians and Surgeons. Illustrated with 118 engravings and two plates. Price: $3.25 net. Philadelphia and New York: Lea and Febriger, 1917.

Any addition to the voluminous literature of poliomyelitis must justify itself first of all. So much literature has collected around the subject that the practitioner is bewildered and prefers to guide himself by the light of some "text-book" description. The writers of this book have set themselves the difficult task of presenting an adequate account of the disease in one volume—and they have succeeded nobly. Beginning with an interesting historical summary, they next define the disease in half a thousand well-chosen words, give a concise, but adequate, description of the pathology, with several excellent plates, and then devote ten pages to that vexed question, the nature of the virus; in so doing they consider all that is worth while in the literature. The writers then go on, after discussing the epidemiology at length, to give an excellent clinical description of the disease in all its aspects, many plates adding to the value of this part. Treatment is thoroughly discussed, especially muscle training and exercise. Especially valuable, we think, is a chapter modestly called, "Some Anatomical and Physiological Reminders"; in this the writers have presented some excellent charts, diagrams and tables whereby the interrelations of neurons and muscles are shown in great detail. The book closes with a table of epidemics of poliomyelitis in the history of the world. Besides being a valuable scientific work, the book is well gotten up mechanically and is not too large for a handy work of reference.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; assisted by Leighton F. Appleman, M.D. Instructor in Therapeutics, Jefferson Medical College, Philadelphia. September 1, 1917. Price, $6.00 per annum. Philadelphia and New York: Lea and Febiger.

The September number of this well known quarterly contains articles on diseases of the thorax and its viscera, including the heart, lungs, and blood-vessels, by W. Ewart; Dermatology and Syphilis, by W. S. Gottheil; Obstetrics, by E. P. Davis, and diseases of the nervous system, by W. G. Spiller. These contributions are, as usual, of a high order of merit; and since the writers have been connected with this publication for several years there is a continuity in their discussions which not infrequently is wholly lacking in works of this character.

CHAIRMAN, DR. F. WEBB GRIFFITH OF ASHEVILLE, NORTH CAROLINA.

Tumors of the Urinary Bladder.—Drs. EDWARD S. JUDD and S. W. HARRINGTON of Rochester, Minn., said that from a therapeutic standpoint bladder tumors might be classified as those satisfactorily treated by endovesical methods and those requiring open operations. There was no question but that the benign papilloma would usually respond to fulguration. Exception to this would be the case of multiple papillomata in which the treatments would be numerous and prolonged, or in case the individual was not tolerant to this kind of treatment. It would be better to do an open operation in either of these instances. It had been customary with them to have all of their bladder tumor cases examined cystoscopically at definite intervals following the original operation with the view of keeping down any suggestion of a recurrence. In the past few years they had found 14 cases of recurrence, following resections, which were amenable to fulguration. One of these patients was fulgurated 15 months following the resection and had been well for two years. One was fulgurated after two years, and had been well for four years. One was fulgurated after 18 months, and the patient now stated, three years after this treatment, that he was well. One was fulgurated after three years, and had not been seen for three months. One had been fulgurated yearly for the last three years for recurrences, and was last examined five months ago. One was fulgurated one month after operation and had not been seen for three months. In case the benign tumor did not respond readily to fulguration, it should be removed by an operation. These papillomata cystoscopically simulated benign growths, and when they did not behave well under fulguration it was a suggestion that they might be malignant. All definitely malignant papillomata, either of the papillary type of carcinoma or of the type infiltrating the bladder wall, were best treated by the open operation at once. All large benign tumors, such as myomata, fibromata, and angiomata, should be removed by suprapubic operation. The operative procedure for tumor of the bladder consisted of excision of the tumor and resection of the portion of bladder wall from which the tumor arose. A simple excision of the tumor was permissible only in the case of a papillary tumor on a pedicle. Even with this form of tumor it was better to excise a portion of the adjoining bladder tissue. Excision of the growth was not sufficient and was no safer than resection. In all cases resection should include the entire thickness of the bladder. This meant the invasion of the prevesical space, but with modern technique it added very little if anything to the operative risk. If the resection was not extensive, the remaining opening could be closed and drainage established through the bladder. If a large segment of bladder was removed it was better to drain the space for several days. The drain could be brought out through the bladder or along the side of the bladder. If the prevesical tissues were exposed drainage was essential. The treatment of bladder tumors was gradually being settled on a definite basis. Much experience with the endovesical treatment had demonstrated the type of tumor that could be cured by fulguration and also the type of tumor that did not respond to this method of treatment. Further experience with the suprapublic open operation had taught them that a radical excision of the tumor, the portion of the bladder wall involved, and the prevesical tissues could be performed with satisfactory immediate and ultimate results.

Hypertrophic Pyloric Stenosis in Infancy.—Dr. WILLIAM D. HAGGARD of Nashville, Tennessee, said that a case of pyloric stenosis presented a picture so characteristic and clear cut that diagnosis should not fail; even a mild case should be recognized, provided every case of vomiting in infancy be given adequate consideration and a careful examination. We had no symptoms of toxemia, or strangulation, and the symptoms and their sequence were classical. Palmer enumerated them in the order of their importance as follows: (1) Persistent, recurrent, explosive vomiting; (2) Starvation stools and diminished urine, with emaciation; (3) Visible gastric peristalsis; (4) Palpable tumor; (5) Bulging epigastrium, with stretched abdomen; (6) Progressive loss of weight. The symptoms might appear within a few days of birth, or be delayed until the second and rarely the third month. They usually appeared during the third or fourth week. Vomiting was the first symptom usually noted. A previously healthy, normal, usually robust male, breast-fed baby, began to vomit abruptly in the third or fourth week without apparent cause. To the persistent, explosive, forcible vomiting was added symptoms of faulty nutrition, constipation, oliguria, and steady loss of weight. The vomiting was characteristic and different from other vomiting in young infants. Visible gastric peristalsis was a constant symptom. The wave passed from left to right, and might be elicited after taking food. Palpation a little to the right and above the umbilicus often revealed a tumor about the size and shape of a small green olive. The tumor was most distinct in the more severe cases with thin retracted abdominal walls. It was variable in its position and might be out of reach under the liver. If every case of hypertrophic pyloric stenosis was operated upon as soon as the diagnosis was established, with the present improved technique, the mortality for this condition, when subjected to operation, might be reduced generally to approach 10 or 15 per cent. Failure to seek prompt surgical relief was too often fatal; even though the baby was apparently holding its own under medical treatment, it might suddenly, and without apparent cause, become progressively worse and die in a short time.

Treatment of Tropical Abscess of the Liver. — Dr. JOHN S. HELMS of Tampa, Florida, said that there was little doubt among those who were experienced in the observation of this disease as to the causal relation between the entameba histolytica and liver abscess of the tropical variety. It must be admitted that there was such a thing as bacterial infection and consequent abscess of the liver separate and apart from amebic infection, and that in most cases where the ameba was the primary cause of the liver abscess there was also a bacterial infection. It had been proven that the ameba of man carried with it pyogenic organisms that might be in the blood stream and find lodgement in the area of lessened resistance of the liver due to the presence of ameba. The general conception was that the abscess was usually a single one, but the experience of the best observers seemed to prove that in about 50 per cent. of the cases the abscesses were multiple. Where the abscess was solitary it was generally located in the right lobe and usually near the convex surface, and in many instances its dome was underneath the diaphragm. After the diagnosis had been made, he believed that there was no other treatment except surgical that gave any certainty of good results. It had been his practice, and he was convinced it had a rational basis, to adopt the open treatment and to effect drainage through the transperitoneal route, and he was convinced after a rather large experience with operation in these cases that it was always practical.

The Treatment of Acute Diffuse Peritonitis.—Dr. H. A. GAMBLE of Memphis, Tennessee, stated that it was his practice to open the abdomen under general anesthesia, remove, or repair the primary lesion, introduce split rubber drainage tubes with gauze wicks into Morrison's pouch, the pelvis, and wherever else indicated, and complete the work as expeditiously as possible. From now on the main indications were to maintain free drainage, promote elimination, sustain the strength of the patient, and guard against complications. The patient, upon being placed in bed, was put in the sitting posture and 500 c.c. of normal salt solution administered subcutaneously. This was repeated every four to six hours (Murphy's method of proctoclysis), with plain warm water, was started also at once. He did not feel that for the first 24 to 48

hours absolute dependence could be placed upon absorption from the rectum and colon. It had been his observation that where there was a profound toxemia the processes of absorption from the intestinal tract had frequently been held in complete abeyance. This also applied at times to the subcutaneous tissues, and he had under such circumstances converted an apparently hopeless case into one which recovered by blood transfusion. Dressings were changed frequently, every one to two hours for the first 24 hours, instead of allowing them to become thoroughly saturated. In the after-treatment of these cases one had constantly to be on his guard for complications, the most important of which in the order of their frequency were acute dilatation of the stomach, secondary abscesses, intestinal obstruction, and phlebitis. Acute dilatation of the stomach was associated with a large proportion of all cases of diffuse peritonitis, and was best treated by frequent gastric lavage, keeping the stomach empty, and the administration of pituitrin. The treatment of other complications was along general surgical or medical principles.

Remarks on Kidney Surgery.—Dr. JOHN R. CAULK of St. Louis read a paper based upon a considerable experience, including 33 nephrotomies or nephrostomies, 50 nephrectomies, 10 pyelotomies, or ureterotomies, 11 fixations, and 3 decapsulations. There had been 40 operations for stone on 36 patients; 17 nephrotomies or nephrostomies; 10 pyelotomies and ureterotomies; 9 primary nephrectomies, and 4 two-stage operations. Twenty-one were done on the right side, seven on the left, and eight bilateral. The symptom of kidney pain had been variable; 28 of the 36 cases had pain; only 17 of these had had colic. There had been 16 nephrectomies for tuberculosis. More than that number were refused operation on account of double involvement, or other complications. Of these 16 cases all were unilateral but 2; these 2 did not improve after operation, and both patients died within 6 months. There had been 29 operations for nontuberculous renal infections, either infected hydronephrosis, pyonephrosis, or pyelonephritis. Of this group there had been 20 primary nephrectomies, and 9 two-stage or secondary nephrectomies. There had been 3 patients on whom a nephrostomy had been done for ureteral ligation complicating pelvic surgery, one a double, two a single ligation. He had done 11 kidney fixations for floating kidney, and in spite of the discouraging results which were credited to this type of surgery his results had been the best of all. There had been 4 nephrectomies for tumor, 2 carcinoma, 2 hypernephroma. Two were done by lumbar nephrectomy, 1 transperitoneal. One patient lived three years and enjoyed two years of excellent health and gained considerably in weight, and died of bone metastases. Another died within two months. Two are living and well, one a year and one a year and nine months after operation.

Latent Manifestations of Syphilis in and About Joints.—Dr. EDWARD S. HATCH of New Orleans drew the following conclusions: "Joint syphilis is much more common than is generally supposed. In the *x*-ray findings and in the luetin reaction we have nearly positive diagnostic aids. An *x*-ray picture, Wassermann and luetin reaction should be made in all suspected cases, and then, if there is doubt, the therapeutic test should be applied. The necessity of this is plain, as the treatment of the diseases likely to be confounded with joint syphilis is quite different from the treatment of that disease."

The Use of Radium in Non-Malignant Uterine Hemorrhage.—Drs. C. JEFF MILLER and E. L. KING of New Orleans presented this communication in which King said that the non-malignant conditions of the uterus causing menorrhagia or metrorrhagia might be grouped as follows: (1) Cases in which there was little or no demonstrable pathologic change in the uterine wall, no history of infection, and in which the uterus was apparently normal in size and position, with normal adnexa. In such cases the bleeding was, in all probability, due to some disturbance of the internal secretions, especially of the thyroid or of the ovary. This condition was often encountered in young girls about puberty. (2) The menopause. (3) Chronic metritis. (4) Hypertrophy, or hyperplasia of the endometrium, especially when so marked as to be adenomatous or polypoid in character. (5) Fibroids, adenomata, or adenomyomata of the uterus. (6) Chronic endometritis, especially after incomplete abortion. (7) Passive congestion of the uterus, as in retroflexion or prolapse. In the first 3 groups radium might be used to the exclusion of surgery; in groups four and five, some cases were suitable for radium, and others required operation; while in groups six and seven, operation was indicated. They had treated ten cases classified under groups 1 and 2. The youngest was in a girl of 16, who had bled profusely for months; the others were in patients from 25 to 46 years of age. In all of them the bleeding had persisted for years. They had all been curetted from one to six times without relief; most of them had also been treated medicinally in various ways; one had had 23 and one 28 *x*-ray treatments. All were naturally anemic and debilitated, especially the 16-year-old girl, who was in bad shape. Nine of them were given intrauterine radium treatments, the average dose being about 1000 milligram-hours. One patient was given a very short treatment, 2¼ hours' treatment, the radium being placed in the upper vagina. The periods became normal, and she was now in robust health. In only one patient did the treatment fail to relieve the condition. In two other cases it was necessary to repeat the treatment. Only one patient suffered from severe menopausal symptoms, although in several of them the symptoms were present in a mild degree. The next 18 cases fell in the third and fourth groups. The patients ranged in age from 30 to 55, and most of them had suffered from bleeding for several years—as a rule, menorrhagia first, and later metrorrhagia as well. In every case examination revealed a large, often tender uterus, with no sign of tumor or adnexal trouble. Of these 18 patients 13 had been curetted from 1 to 4 times, and 7 had had other operations on the uterus or adnexa performed at the same time, all without relief. One of these had also had subsequent *x*-ray treatments, with no improvement. The other 5 had been treated medicinally in various ways, including packing. In every case radium treatment was followed by amenorrhea: in two patients there was a recurrence of the bleeding about one year later, the flow being approximately normal. The others were still relieved. Six patients suffered from marked menopausal symptoms; 5 others were similarly affected, but the symptoms were mild and transient. The patients suffering most from the artificial menopause were nearly all between 40 and 51; this coincided with the author's experience after hysterectomy. In three women, aged 35, 45, and 51, the condition was relieved by corpus luteum extract. Eight patients suffered from leucorrhea for 2 or 3 months after the treatment. In those cases in which subsequent pelvic examinations were made marked reduction in the size of the uterus was found, and the tenderness, as a rule, disappeared. The dosage in these cases was 500 to 1000 milligram-hours. Their results had been and were most gratifying, and they believed there was a definite field for radium therapy in the treatment of these annoying and often obstinate affections. It was not a cure-all, but its judicious use would often obviate the necessity of a mutilating operation with the attendant risk to the patient, whose well being should be our constant aim.

Interpretation of Lumbosacral Backache in Women.—Dr. EDWARD H. RICHARDSON of Baltimore said that the determination of the specific cause of lumbosacral backache in a woman involved a careful study both in the domain of the orthopedist and in that of the gynecologist. In the former we must scrutinize the lower spine, the lumbosacral, and the sacroiliac articulations very closely for evidences of arthritis, of injury, and of chronic strain from one or more of the causes enumerated above. In the latter the point to remember was that, with rare exceptions, whatever the nature of the particular gynecological disorder, it produced lumbosacral backache only through the strain incident upon faulty posture, and that no matter how skillfully our operative therapy might be, it would often fail utterly to relieve the backache unless supplemented by orthopedic measures which would restore normal balance.

Tetanus Treated by Subarachnoid Injections of Magnesium Sulphate and Antitetanic Serum; Recovery.—Dr. DEWITT B. CASLER of Baltimore presented a paper of which the following were the conclusions: "(1) Certain patients are definite tetanus carriers, and, as such, are liable to be a source of infection to themselves in any surgical operation on the bowel, or about the rectum. (2) In any abdominal operation, especially in pelvic work, where the surgeon has to deal with inflammatory masses, indurated and adherent to the bowel wall, great care should be taken to close in this indurated area as thoroughly as possible, and so avoid the danger of tetanus developing in the injured bowel wall. (3) It is wise in every case of postoperative tetanus to begin at once subcutaneous injections of magnesium sulphate, and in the severe cases subarachnoid injections. (4) It must be borne in mind that there is always a certain amount of danger from paralysis of the respiratory center, and when subarachnoid injections are given, means for artificial respiration should be at hand. (5) Magnesium sulphate given intraspinally affords the greatest amount of comfort and relief to those cases, where death often comes, not only from the toxemia but from exhaustion."

The Rôle of Syphilis in Surgery.—Dr. GEORGE GELLHORN of St. Louis said that he had seen extensive suppurations of the abdominal incision resist all possible treatments for weeks, but turn into clean and vigorously granulating wounds as if by magic when antiluetic treatment was instituted. He recalled four cases in which the entire abdominal incision broke open about a week after operation. The tissues of the abdominal wall showed no tendency whatever to unite, but there was no suppuration present. All four patients were profoundly cachectic. Two were probably not luetic, but one was a frank syphilitic, and the fourth, despite a negative Wassermann, was probably diseased. It would be interesting and important to know how high the percentage of syphilis was in such cases of complete disinclination of the tissues to heal. He had at present under his care a woman with tertiary syphilis, in whom several surgeons had unsuccessfully attempted to repair a third degree laceration of the perineum. He subjected this patient to energetic antisyphilitic treatment with the view of softening the cicatricial tissues about the vulva and of forestalling disturbances of wound healing. In the course of this treatment, which included several injections of salvarsan, a laparotomy for pus tubes became necessary; and the patient went through this operation without the slightest complication.

(*To be continued.*)

FIRST DISTRICT BRANCH OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eleventh Annual Meeting, Held in Newburgh, November 9, 1917.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. RICHARD GILES OF COLD SPRING, IN THE CHAIR.

(*Concluded from page 963.*)

Intermittent Hydronephrosis and Pyonephrosis in the Female.—Dr. DOUGAL BISSELL of New York made this presentation. He said that for the purpose of convenience he would use the word nephrectasis when referring to distention of the kidney pelvis without regard to the character of the fluid, for the condition to be considered was mainly one of hydrostatic pressure, whether the contents of the tumor was urine with or without pus. Inability of the ureter to accommodate itself to the urinary stream, as the result of stricture, stone, papilloma, or the pressure of a body from without, such as a fibroid tumor or a pregnant uterus, constituted factors in the causation of nephrectasis, but abnormal mobility of the kidney with angulation of the ureter or with transient polyuria were the important causative factors in the intermittent form. It was the rule in cases of prolapsed kidney for the upper or abdominal portion of the ureter to descend with the kidney, the degree of prolapse of the ureter following closely the degree of prolapse of the kidney. When this was not the case the curve of the ureter became more and more marked until an acute angulation of the ureter might form with resulting interference with the drainage and damming back of the urine in the pelvis of the kidney. Intermittent nephrectasis might be of two types. It might occur daily or at irregular intervals. The daily type was perhaps without exception due to abnormal mobility of the kidney associated with acute angulation of the upper portion of the ureter. The type occurring at greater intervals had as its causative factor partial obstruction of the ureter, upon which was superimposed at intervals transient polyuria. A calculus in the ureter might occasion a partial or complete distention of the kidney pelvis but its presence alone never accounted for intermittent nephrectasis. A stone in the ureter must terminate in one of three ways, partial obstruction of the urinary stream, complete obstruction with or without necrosis of the ureter, and extravasation of the urine into the perirenal tissue, or expulsion of the stone. A supernumerary or accessory renal artery passing in front of the ureter was considered by many authorities as an etiological factor in nephrectasis. The importance of the accessory artery as a causative factor in nephrectasis the essayist had never been able to demonstrate to his own satisfaction. As the nephrectasis of pregnancy occurred at definite periods in the life of the female it might be considered as coming within the scope of this paper. The anatomical and mechanical reasons for this form of renal pelvic distention, as commonly accepted, were to the author's mind not satisfactory and seemed to him unsupported by facts. In discussing the diagnosis of cases of nephrectasis, when the tumor had reached a palpable size and its anterior surface was in apposition with the anterior abdominal wall, Dr. Bissell said we usually expected to find resonance immediately over the tumor and dullness in the flank, but the location of dullness varied (1) with reference to whether the right or left kidney was involved, (2) with the extent of mobility or fixity of the kidney, (3) with the amount and direction of the distention of the kidney, (4) with the amount of gas in the colon the time of the examination, and (5) with the extent of fixity or mobility of the cecum and ascending colon. The study of a large group of movable kidneys through the median abdominal incision had led the essayist to the conclusion that not infrequently the right prolapsed kidney was located well to the outer side of the colon whereas the left prolapsed kidney usually remained posterior to the colon. Therefore, when there was superimposed upon this malposition of the right kidney a marked distention, the colon might be forced well toward the median line, but the relative position of the left kidney to the colon under similar conditions usually remained practically the same. Intermittent nephrectasis might be mistaken for renal abscess, single or multiple cystic kidney, hypernephroma, or extravasation of the urine into the perirenal area, for tumor of the ovary, liver, gallbladder, or spleen. The differentiation was, however, not difficult if the history pointed to a subsidence and recurrence of the tumor at more or less regular intervals. In differential diagnosis the history regarding intermission or non-intermission was the chief consideration. In considering the treatment of intermittent nephrectasis, it should be remembered that the condition might subside after one or two attacks and not recur. Such, however, was not the rule if the sacculation of the pelvis of the kidney had been of considerable size. Treatment with the curative object in view must depend upon the cause and, if the cause of distention could not be determined or if having been determined it could not be remedied, nephrectomy, when the remaining kidney was normal, was the procedure of choice; but if the patient had but one kidney, the kidney sac should be opened and a fistula established. The objective signs of an abnormally movable kidney were so unmistakable, and the subjective symptoms so characteristic and disturbing, that the scant consideration given to the surgical treatment of the ptosed kidney seemed incomprehensible. To those who did not believe in the operation of nephropexy from the standpoint of relieving certain subjective symptoms, the

author suggested that they consider its advisability as a prophylactic means, not only with the object of correcting the cause of interference with the flow through the ureter, and thus preventing nephrectasis, but with the object also of eliminating renal engorgement which might act as a causative factor in tuberculosis of the kidney.

Dr. J. Wilson Poucher of Poughkeepsie said that Dr. Bissell had so fully given everything with reference to the symptoms, diagnosis, and treatment of intermittent distention of the kidney, that it seemed to him that any remarks on his part would be superfluous. He wished, however, to thank Dr. Bissell for having brought out certain points. One of these was that over-distention of the pelvis of the kidney was practically always due to angulation of the ureter caused by malposition of the kidney and that relief was due to the kidney being lifted to its proper axis when the pelvis would be emptied. Dr. Poucher said his first introduction to a case of hydronephrosis when he was a young practitioner was when he was called to attend a lady and found her suffering from very acute pain and the entire abdomen symmetrically distended. The case appeared to be one of abdominal ascites. He gave the woman a large dose of morphine and decided to call an older surgeon into consultation. The case looked very much like one of acute peritonitis for which nothing could be done. When he called to see the patient later in the day he found her sitting up and the kidneys relieved. She had passed large quantities of urine and the abdominal distention had disappeared. He then discovered that this woman had a kidney with considerable mobility. He advised a nephropexy, which the patient declined. After a short time the experience just related was repeated and then the woman was ready to submit to an operation. That was done twenty years ago. The woman was living today and there had been no recurrence of her trouble. In all cases of intermittent hydronephrosis uncomplicated by stone, tuberculosis, or of the opposite kidney, nephropexy would prevent a recurrence of the condition. As to the causes that produce angulation or obstruction of the ureter Dr. Bissell's description of his theory was the most up-to-date which the speaker had heard. He had known a woman who had moderate attacks of distention and hydronephrosis and they were due to the twisting of the kidney on its axis so that it lay up on edge and the symptoms were always relieved by getting the kidney into its proper position. This woman finally had a nephropexy performed some ten years ago and was cured. There was just one point which Dr. Bissell did not mention, and that was that one rarely found a hydronephrosis of this character in a kidney that moved all the way over to the median line or all over the abdomen. Pyonephrosis or hydronephrosis produced by stricture, either in the kidney or ureter or by tuberculosis, as was sometimes found, the treatment was always a proper nephrectomy, though, as the speaker understood, the province of Dr. Bissell's paper was limited to the consideration of hydro- or pyonephrosis due to movable kidney. It had been the experience of all general surgeons who had done any great amount of work on the kidney that they usually found some other condition in addition to the stricture, either a tuberculosis of the kidney or some other condition interfering with the function of the kidney and in most of these cases in which a primary nephrotomy was done it was necessary later to do a nephrectomy.

Dr. H. Dawson Furniss of New York said he thought we did not now see so many of these cases of extreme hydronephrosis as Dr. Bissell and Dr. Poucher had reported. Such cases were now receiving attention earlier and consequently did not reach this extreme stage of dilitation of the renal pelvis. They had learned to diagnose these cases earlier and to give them the advantage of treatment in the beginning and thus save the kidney. Every case that came complaining of renal colic showed evidence of obstruction, which might be due to stone, to tuberculosis, to movable kidney, or stricture of the ureter. Acute pain meant obstruction of the ureter, and the nature of the obstruction could be determined by one or more of the various methods at our disposal. Caldwell had shown that only about 5 per cent. of renal or ureteral calculi were not demonstrable by the *x*-ray. This 5 per cent., if the stone was in the ureter, might be demonstrated by the use of the wax-tipped catheter, or by the pyelograph or the ureterograph. As to the location of the ureteral obstructions, Hunner reported that he had made observations on this point in 100 cases, and he found that in the vast majority the obstruction was in the lower end of the ureter, within the first two to five centimeters from the lower end. As to the cause of the stricture, it might be due to a hematogenous infection from a phlegmon, from tonsillitis, from chronic appendicitis, or might occur after the removal of a stone. In one case in which a stone was removed last February there was recently an obstruction at the lower end of the ureter. He had seen several other similar cases recently. There was no question but that in the majority of cases the obstruction would be found at the lower rather than the upper part of the ureter. The speaker said he had seen no cases in which the obstruction could be said to be due to the pressure of the pregnant uterus or to a growth, but he had seen instances in which it occurred after operation where the broad ligaments were involved, thus producing stricture or angulation. Many cases of stricture or obstruction had intermittent colic, and it might come on with such regularity that the patient could predict with certainty the attacks. In the diagnosis of these cases we should remember that every case with renal colic had not necessarily stone. At the first examination the patient should not be cystoscoped, but should first be examined for the presence of pus, blood, etc., and the character of the infection, if present, ascertained. Then there should be an *x*-ray examination for calculi. After that the patient should be cystoscoped, after giving indigo-carmine 10 c.c. of a 0.3 solution intravenously. Normally this appeared within three to six minutes. If it showed on one side and not on the other, we knew that we had something inhibiting the flow. If it was not due to a calculus and there was no tuberculosis, it might be due to pressure atrophy as a result of stricture. Having determined that obstruction of the ureter was present, the next point was to determine where the obstruction was located and the degree of the obstruction. In the majority of cases this could best be done by means of catheters (No. 5 or 6 French). As to the use of thorium nitrate injections, by this means one obtained an *x*-ray picture showing the silhouette of the inside of the kidney. However, one should be cautious about making a pyelograph except in a hospital. In normal individuals these injections caused no pain, but in cases in which there was a certain amount of obstruction present the irritation caused by the injection might bring on an acute attack of retention. A retention brought on in this way was more dangerous than that of one of urine alone. Still pyelography and ureterography remained the best and most accurate methods of diagnosis of stricture. Having determined, therefore, that there was an obstruction and the point at which it was located, the next point to be settled was what procedure to adopt. That would depend upon the location of the obstruction, the cause, the amount of infection, and the degree to which function was interfered with. The degree of impairment of kidney function was more important than the amount of infection. If the function was greatly impaired, Dr. Furniss said he was in favor of taking out the kidney, provided the remaining kidney was functioning well. In cases in which the obstruction was due to movable kidney and the ureter was more or less fixed and there was dilatation of the pelvis of the kidney nephropexy was indicated. It had been found that in the majority of cases the stricture was in the lower end of the ureter, and the point here was whether this stricture could be dilated so that operation would not be necessary. Personally the speaker said he was unable to keep these ureters sufficiently dilated. He had used a 20 French catheter and yet they had become small again. In four cases he had performed a ureterovesicular anastomosis with satisfactory results. By functional tests, *x*-ray examination, a combination of thorium and *x*-ray test, one should be able to determine whether a stricture was present, where it was located, and whether the kidney was worth saving.

Dr. Bissell, in closing the discussion, said that in answer to Dr. Furniss' question as to the length of time that these patients had suffered from their

nephrectasis, he had been correct in supposing that they were old cases; one had had symptoms of the trouble for four years and the other for ten years. He thought they were pretty much in accord as to the causes of this condition and that the explanation that pressure on the ureter might be one of these causes was correct. Dr. Poucher had made the remark that the essayist was up to date in his theory with reference to angulation of ureter being caused by the failure of the ureter to follow the prolapsed kidney. This was not altogether a new theory. It had been suggested by a French physician, Pignon, in 1856, but he had not been able to support the theory with proofs as well as had been done recently. He was perfectly right in assuming that the kidney might prolapse and the ureter not prolapse in some instances. The reason was that when one found a movable kidney the ureter usually took the same motion and accommodated itself to the position of the kidney, but when it did not do this an angulation of the ureter occurred and a damming back of the urine into the pelvis of the kidney resulted.

Acute Abdomen.—Dr. JOHN B. DEAVER of Philadelphia read this paper, in which he considered acute abdomen more especially in reference to acute perforations of and gangrene of the appendix, perforating gastric or duodenal ulcer, acute perforating and gangrenous cholecystisis, acute hemorrhagic pancreatitis, and acute intestinal obstruction. He stated that the most common type of acute perforation into the abdominal cavity was that of the appendix. When perforation occurred, whether the process had developed suddenly or slowly, the primary consideration was not the treatment of the lesion in the appendix so much as that in the peritoneum. Within the first 24 hours of any peritonitis the process was confined and at this stage amenable to surgical interference. The operative mortality at this stage was about 1 per cent., but it rose rapidly if first seen after that period. Some of the guiding signs that indicated when an appendicitis went over into a peritonitis were persistence and exacerbation of the pain and tenderness in the right iliac fossa, extension of the tenderness, increase in pulse rate and muscular rigidity, and absence of peristalsis. After discussing the misleading character of the symptoms of gangrene of the appendix, Dr. Deaver stated that next to perforation of the appendix the most common cause of the acute abdomen was a perforating chronic gastric or duodenal ulcer. Here the pain was of an acute stabbing character referred to the upper abdomen. A downward course of the infection sometimes led to the error of accusing the appendix of being the source of the trouble. With the escape of fluid through the perforation into the abdominal, the pulse rate rose, the abdomen became distended, and intestinal obstruction became almost complete. As tenderness became more marked the symptoms of shock were followed by collapse. As a rule after the first onset of pain the patient vomited only once. This was an important distinction between perforation and obstruction or strangulation of the bowel. While the symptoms indicative of perforation into the peritoneal cavity were characteristic, they did not designate what part of the gastro-intestinal canal was affected. The previous history was, of course, important, and, if this were always clear and always obtainable, there would be little difficulty in making the distinction. The symptom complex of an acute perforation of a chronic ulcer, whether situated in the duodenum or in the anterior wall of the pyloric antrum, was the same. If presented by a young, anemic female the chances were in favor of the gastric location; if in an adult male, the site would be more likely to be found in the duodenum. In case of hemorrhage, the ulcer would more likely be found in the gastric location. It was not generally possible to make a pre-operative determination of the position of a perforating peptic ulcer, nor was it important; the most essential point was to prevent the catastrophe by proper treatment, surgical, as a rule, of the underlying causes that led to it. What ignoring danger signals mean was perhaps best illustrated in acute perforating or gangrenous cholecystitis. Mayo had called attention to the fact that perforation of the gall-bladder had been one of the most fatal of the different types of acute perforation. He attributed this to the fact that the cases came to operation late, because the patients having had one or more attacks of gallstone colic considered the attack merely a repetition of such an attack and surgery was not resorted to until too late. Infection was the primary factor in acute cholecystitis. An infected gall-bladder seldom, if ever, regained its normal condition, and subsequent acute or chronic inflammation and the formation of gallstones were the phenomena to be expected. In most instances the severer forms of infection occurred in connection with cholelithiasis. The chief danger of a suppurative cholecystitis was a perforation. The appendix was often involved and might also perforate. Another lurking menace of repeated inflammation of the gall-bladder was the effect on the pancreas. The overwhelming, sudden seizures of the acute abdominal conditions thus far discussed were repeated and exaggerated in the symptoms of acute pancreatitis. The mortality of this disease was high if unoperated upon and high enough (23 per cent.) in operated cases. Acute pancreatitis usually fell into three types, ultra-acute, acute, and subacute. The prognosis in the first two types was bad. Subacute pancreatitis was the more common type of the disease and was more amenable to treatment. Fortunately this condition was among the less frequent causes of acute abdominal crises, for it might be said to head the list as far as exquisite suffering and unfavorable prognosis were concerned. Intestinal obstruction, exclusive of intussusception, was said to be the cause of one-fourth of the cases of acute abdomen. The symptoms did not differ greatly from those of perforation of a hollow viscus. Vomiting, however, was more persistent and continuous. The pain was distinguishable from the pain of peritonitis by being so much more susceptible to palpation than to percussion; the rigidity so typical of peritonitis was usually absent, and there was total obstruction of the bowels. The patient was also restless and tossed about. The important point in connection with intestinal obstruction was to recognize the condition and to bring it to operation at the earliest possible moment, before septic absorption and inflammation led to a grave and hopeless peritonitis. The greatest factor in the mortality of peritonitis was undoubtedly delay in surgical intervention, and next in importance was faulty method of treatment at the onset of acute conditions preceding the peritonitis. The main point in caring for the latter was complete physiological and anatomical rest. No food should be given by mouth, and above all nothing in the nature of a laxative or purge. In a series of 259 operations for acute appendicitis, 79, or 30.5 per cent, had been purged before admission. At operation in all but two of these cases the appendix was either perforated, gangrenous, acutely ulcerated, or surrounded by an abscess. There were seven deaths in the series and five of these had been purged before admission. It was important to direct the spread of infection downward toward the pelvis by the Fowler sitting position. Another pre-operative measure of immense value was the Murphy method of enteroclysis. Icebags were of value only in relieving pain and lessening peristalsis, not in reducing inflammation. During the interim of undetermined diagnosis the important thing was to follow the Hippocratic dictum to do no harm. A forced enema should be avoided, as it had been known to send the fluid through the perforation into the peritoneal cavity. In appendical peritonitis of less than 40 hours' duration immediate operation had given the best results. In cases of appendical perforation with progressing peritonitis of more than 40 hours' duration delay was the best policy. Lavage of the peritoneum was unnecessary and harmful. The pus should be removed in the gentlest manner, care being taken not to disturb the protecting coat and lymph. Every case of perforating peptic ulcer operated on within the first 24 to 48 hours should get well. The essayist stated that he had operated on 51 such cases with one death. It was his practice to perform a primary gastrojejunostomy after closing the perforation. In the treatment of acute gall-bladder conditions cholecystectomy was the operation of choice when concomitant circumstances made this operation feasible. Removal of the gall-bladder not only greatly lessened the chance of recurrence of gallstones, if such were present, but also cured pancreatitis and pancreatic lymphangitis, the

forerunner of disease of the pancreas. In fulminating ultra-acute pancreatitis early operation was imperative in order to give the patient a fighting chance, but in general it was an advantage to wait and give the body a chance to prepare itself for a still greater tax upon it. Dr. Deaver also discussed the relative values of the intra- and extraperitoneal routes for operations on the pancreas.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

One Hundred and Twelfth Annual Meeting, Held November 26, 1917.

THE PRESIDENT, DR. J. BENTLEY SQUIER, IN THE CHAIR.

EXECUTIVE SESSION.

Report of Counsel.—Dr. GEORGE W. WHITESIDE submitted this report, in which he stated that the field of investigation and prosecution during the past year had been wide and varied. Investigations had been made and prosecutions conducted against druggists who had been practising medicine, unlicensed physicians from foreign countries and other parts of the United States, corporations, electrotherapeutists, face specialists, and chiropractors. During the year a very thorough investigation of chiropractice in this country had been made and the investigators had been able to successfully prosecute several chiropractors. The counsel had secured 35 arrests during the year and had obtained 24 convictions. Twenty of the persons convicted were fined sums varying from $25 to $150, and three who were convicted were given jail sentences. One case which the counsel considered of special interest to the profession was that of the Gatlin Institute of New York, Inc., and William A. Godfrey against the society. The history of the case was, briefly, that Godfrey had been hired by the corporation, that he was prosecuted by the society, and acquitted by the Court of Special Sessions. The Gatlin Institute then brought a suit against the society to recover damages for false arrest and malicious prosecution and recovered a judgment against the society for $2,500, which judgment was appealed from the Appellate Division. In the prosecution against the Gatlin Institute as a corporation, it was charged that the institute as a corporation was unlawfully practising medicine and that they were aided and abetted by Godfrey. The question involved in the case was whether a corporation could hire a registered physician to make diagnoses and prescribe treatment and thus enable the corporation to carry on the practice of medicine. Godfrey contended that there was no holding out on his part to practise medicine and that neither he nor the institute was practising medicine. The counsel, on the other hand, held that both Godfrey and the institute were practising medicine in that they were treating the drink habit. Among the questions raised by the counsel on appeal were: "May a corporation under the Business Corporation Law practise medicine or may it do so by employing registered physicians, who receive a salary from the corporation, treat patients, or diagnose their cases, and is such treatment a violation of the section defining medicine and the Public Health Law?" The Appellate Division reversed the judgment awarding Godfrey damages and dismissed the complaint. The Court, after a review of the facts, upheld all of the contentions raised by the counsel, and Judge Mills expressed the opinion that the case was one of great importance, as being likely, if it stood, to lead to the opening of many quack sanatoriums and "cure-all" institutes under guise of business corporations or registered trade names of individuals who were licensed physicians. The Court held that Godfrey and the institute should have been convicted and pointed out that the examination and prescription by the licensed physician was a sham employed by the institute. The counsel reviewed the other cases prosecuted during the year, and stated that in addition he had given general aid to the Comitia Minora and the Board of Censors in their work, and had also given legal assistance in the problems which they had brought before him. He had prepared a paper on the proposed Medical Practice Act drawn by the State Board of Medical Examiners and a committee from the State Medical Society, having the approval of the Board of Regents and the counsel of the State Society. He had cooperated when it was possible with the various departments of the State and city governments in connection with improvements in the Medical Practice Act, and various of these departments had cooperated with him.

Report of Committee on Public Health.—Dr. FRANCIS CARTER WOOD submitted this report. He said that the only matter brought before the committee during the year 1917 was a request from the New York Social Hygiene Society that the committee express an opinion on Assembly Bill No. 309, an act to amend the Penal Code in relation to advertisements concerning venereal disease. Believing that this was a matter that properly belonged to the Legislative Committee they referred it to that committee and learned that it was already being considered by that committee.

Report of Committee on Legislation.—Dr. GEORGE W. KOSMAK submitted this report in which he stated that the regular number of meetings had been held during the session of the Legislature in January, February, March, and April. Representatives of the committee had appeared at the hearings on compulsory health insurance and the antinarcotic drug bill. A special meeting had been held to consider the Assembly bill with reference to the publication of advertisements dealing with the treatment of venereal disease. The Social Hygiene Society was very desirous of obtaining the support of the committee, and the bill as amended was finally passed. The object was to eliminate advertisements of this character from the newspapers and magazines, but the bill resulted in restricting reputable advertisements in medical journals. Publishers had had the matter under careful consideration, and it was probable that some action would be taken when the Legislature met again. While the purpose of the original bill was well intentioned, its failure in construction might result in the repeal of the recent amendment to the Penal Code relating to this question. It was to be hoped that some arrangement could be made whereby the unjust features of the bill could be eliminated. In reviewing the character of legislative actions of interest to the medical profession it was stated that the principal matters of interest taken up by the State Assembly were the bills relating to compulsory health insurance and the question of narcotic drugs. In no case had final action been taken, and it was probable that these questions would again be considered. The usual bills for admitting members of special sectarian organizations to practise medicine were introduced and defeated, and no important amendment to the Medical Practice Act was added. The above reports were all accepted by the Society.

Minority Report from Legislative Committee.—Dr. CHRISTIAN F. J. LAASE presented this minority report in which he endeavored to show the difficulties under which the Legislative Committee labored and that through no fault of the personnel of the committee, but rather through faults of the method of administration, the work of the committee was not as effective as it should be. He presented resolutions embodying the suggestion that the by-laws of the society be changed so that legislative matters affecting the medical profession should be brought before the Society as a whole for discussion, instead of being referred to the Comitia Minora. This report was received and placed on file.

Report of the Milk Commission.—Dr. ROLAND G. FREEMAN submitted this report. He stated that the Milk Commission was supervising 14,598 quarts of milk, produced on twenty-four farms. The inspector had made 2,652 visits during the year, and in addition had spent 89 days in the laboratory. Twenty-eight tuberculin tests had been made requiring 56 days' work. The experimental production of goat's milk referred to in last year's report had been continued and the number of goats increased so that at present quite a large supply of goat's milk was available for observation in our institutions. It was being supplied to several institutions where pediatrists were making comparative studies on the efficiency of cow's milk and goat's milk to determine whether it was desirable to have a permanent supply of goat's milk for babies who did not do well on cow's milk.

Public Health Education.—Dr. ESTHER L. JEFFERIS

submitted this report, which was read by the Secretary. The report stated that the eighth annual series of lectures for the public on the prevention of disease had been given, eignt meetings having been held from February 6 to March 29, 1917. The total attendance averaged about 2,500. The usual hearty cooperation had been received from the members of the Society, the Department of Health, the Bacteriological Laboratory of Cornell Medical School, Yale University, and the Mutual Life Insurance Company, which had contributed speakers. The newspapers had contributed their quota of advertising assistance upon which the committee during their last eight years' experience had learned to depend.

Secretary's Report.—Dr. DANIEL S. DOUGHERTY submitted this report, which showed that the membership of the Society at the present time was 2,779. This was an increase of 47 over the membership of the previous year.

Resolutions.—Dr. ARTHUR F. CHACE presented resolutions protesting against Section 209 of the excess profits tax. He pointed out that this Section imposed an excess tax of 8 per cent. on all incomes ot over $6,000 derived from labor while that tax was not imposed on incomes derived from investment or in other words from "loafing." The professional man was taxed for working, and he was so situated that if he entered the service his income from his practice stopped entirely. These resolutions were adopted by the Society and will be presented at the coming session of Congress.

Dr. FREDERIC SONDERN presented resolutions in which he pointed out that Section 105 of the Sanitary Code, regulating diagnostic laboratories, gave the Health Department power to inspect the records of such laboratories, and that these might be used as a means of ascertaining whether communicable diseases were being properly reported. The resolutions were to the effect that such records were to be regarded as confidential, and that a physician was under no obligations to open them for inspection by the Health Department. These resolutions were adopted.

Dr. JOHN P. DAVIN presented resolutions to the effect that whereas the aims of the County Society were identical with those of the Health Department, namely, the betterment of health conditions, and since the profession had had to contend against measures and methods which were inimical to the interests of the profession and whereas such measures were promulgated without the knowledge of the organized medical society, this condition should be obviated by the appointment of a committee from the Society which should cooperate with the City Administration and the Health Department selection of public health officials and in the promulgation of measures affecting public health.

SCIENTIFIC SESSION.

The Clinical Value of the Complement Fixation Test in Tuberculosis.—Dr. HYMEN R. MILLER presented this communication. He said it was demonstrated a number of years ago that the complement fixation reaction for tuberculosis was feasible. The test held out practical possibilities only within the last few years when fresh interest in the subject was quickened by the newer work of many research men. The difficulty centered about the production of a suitable antigen. Best results seemed to have been obtained by the antigens of Calmette, of Besredka and his followers, Bronfenbrenner, Craig, etc., and of Petroff. With these antigens, however, not infrequently there was false fixation of normal and luetic sera. In February, 1916, Mill and Zinsser proposed a simple antigen which had been described elsewhere, made up of ground tubercle bacilli in physiological sodium chloride solution. This antigen was prepared by taking 20 mg. of the moist tubercle bacilli mass, placing it in a conical centrifuge tube, and adding to it 90 mg. of table salt. With a glass rod, filed to roughness at the end, this paste was ground by hand for about one hour. Distilled water was then added to isotonicity, that was 10 c.c. to the above mentioned quantities. This was the antigen. Just before using, it was shaken up and the heavier particles allowed to settle in the course of a few minutes. Except for the removal of these large elements the suspension was used as a whole without centrifugation and without filtration. With this antigen well over 3,000 serums had been tested. The reaction was practically never positive in normal and non-tuberculous patients. It was negative in from 80 to 90 per cent. of clinically arrested cases. It was positive in the very largest number of incipient cases, of first and second stage (Turban classification), and in a considerable number of third stage cases. The reaction became negative before death, also when the clinical course of the disease indicated improvement. The complement fixation test was independent of tuberculin skin reactions. The test indicated the presence of active disease. The reaction was negative in luetics unless there was active tuberculosis present.

Dr. ALFRED MEYER said that his interest in this work had begun about the same time that Dr. Miller began his investigations. His work, however, had been along the clinical side, while that of Dr. Miller had been entirely laboratory work. He had been sending Dr. Miller material from three sources, 85 cases in all. The largest number of cases came from the Bedford Sanitarium of the Montefiore Home, an out-of-town institution; others came from Mount Sinai Hospital, and the remainder from his private practice. These 85 cases fell into three classes; the first group consisted of 48 cases with a positive sputum and definite symptoms of tuberculosis. Of this group 96 per cent. gave a positive complement fixation reaction. A second class of patients, numbering 15, had negative sputum but were nevertheless probably tuberculous, and these gave a positive complement fixation reaction in every case. There were 22 cases of other diseases, mostly thoracic, probably not tuberculous, and of these 68 per cent. gave negative reactions to the complement fixation tests. There were cases of pleural effusion, pulmonary tumors, valvular lesions, and one of diabetes. Two cases in class two ought perhaps to be excluded, because in the one there was a four plus Wassermann and the possibility that the Wassermann test and the complement fixation test for tuberculosis might overlap, and in the other there had been some tuberculin tests with constitutional reaction a short time before. There were three cases in the entire series in which the conclusions conflicted and these could not be explained. Craig reported 150 cases of syphilis, of which only two gave a positive tuberculous complement fixation test; in these Craig said there might have been a combination of syphilis and tuberculosis. Dr. Corper, after a study of 327 sera, had stated that no conclusions should be drawn from a positive complement fixation reaction for tuberculosis if a positive Wassermann was present, but he gave no clinical evidence, and hence Dr. Meyer felt inclined to accept his statement with hesitation. In the speaker's series there were three cases that gave a positive Wassermann and two of them a four plus reaction, and with one exception they gave a negative complement fixation reaction for tuberculosis. One, however, also gave a positive complement fixation for tuberculosis. This patient then had an *x*-ray plate taken, but the roentgenologist would not commit himself to an opinion as to whether tuberculosis or syphilis was present in the lung. Dr. Meyer said he thought it wise to withhold final opinion in this test, but he felt from his personal experience with it that it had come to stay; he would insist, however, that in order to come to a dependable conclusion as to its value Dr. Miller's technique be followed with absolute accuracy down to the minutest detail. Any deviation from the published description, however slight, might vitiate the results and would be manifestly unfair.

Dr. FRANCIS CARTER WOOD said that those who had lived a long laboratory life had had a wide and variegated experience of the appearance and disappearance of tests, and that it was perhaps well to moderate enthusiasm in the presence of a new one. It was an extremely difficult matter to apply a laboratory method to a disease as complex and variable as tuberculosis—even more variable than syphilis. One should be very careful in judging of the clinical activity of the tuberculous process by comparison with the strength of the complement fixation reaction, which was known to be extremely rough. It should be remembered that possibly the clinical activity might be due to the presence of other organisms and allowance should be made for this. Any one who had done autopsies on old cases of

tuberculosis understood why certain late cases did not give any reaction to the complement fixation test. Seeing these old cavities, it was evident how little absorption could take place from them because of their thick, fibrous walls, and it could also be seen why the tubercle bacilli might be found in sputum when the complement fixation test was negative. It would be interesting to give injections of tuberculin to mobilize the toxins in individuals who had given negative reactions and then test them again and see what difference the tuberculin made. Dr. Wood understood that Dr. Miller did not get a positive fixation test in animals after the injection of tuberculin. Finally, Dr. Wood said that as we were discussing another test requiring the drawing of a considerable quantity of blood he would like to urge upon teachers of anatomy and surgery the importance of teaching the anatomy of the superficial veins of the arm and the proper method of inserting a needle therein. If this were done one would not see so many sloughs and undesirable results from the attempt to inject salvarsan or other therapeutic agents into the superficial veins of the arm nor so often see repeated punctures and a bloody condition of the patient and bed as a result of the efforts to extract a few c.c. of that now most important diagnostic fluid.

Dr. Emanuel Libman said he had had a very limited experience with this method as carried out by Dr. Miller, but he had kept in touch with Dr. Miller's work. He had, however, tested some cases in the wards of the hospital. To have had, as Dr. Miller reported, only two positive results in 1400 tests looked as though a positive reaction meant that tuberculosis was present. He would like, however, to see someone else take the patients in a hospital ward and give every one a Wassermann and a complement fixation test and then to compare the findings with autopsy findings; they had thus far had no autopsy findings in cases given the complement fixation test. It seemed from the evidence at present that one practically never got a positive reaction in a case that did not have tuberculosis, excepting as Dr. Miller had observed, that in old or well-advanced cases of tuberculosis one was likely to get a negative reaction. To be of value in a given case it was important to know how often one should make the test, because there might be a variability of the test in the same patient at different times. As matters now stood, it seemed as though a positive reaction indicated the presence of tuberculosis, but it was important to know that a negative reaction did not exclude active tuberculosis.

Dr. Abraham Garbat said that he had had the good fortune to be able to follow out the clinical side of this test and to make the tests himself. This they had been doing at the German Hospital for the past six or seven months. Most of their material had consisted of cases of non-pulmonary tuberculosis, as tuberculous infection of the peritoneum, kidneys, bladder, bones, joints, etc. He refrained from giving percentage results because he felt that at the present time it would not be conclusive, in view of the comparatively small number of cases. However, he had come to the conclusion that the complement fixation test was a distinct aid in the diagnosis of doubtful conditions. It would be necessary to settle the question of relationship between a positive reaction and an active process in these non-pulmonary infections; for example, in a case of tuberculosis of the glands it was of the greatest importance to decide whether one was dealing with an active process or not. With reference to the question of non-tuberculous cases giving a positive reaction, the speaker stated that he had not found one non-tuberculous patient who gave a positive reaction. Dr. Libman's suggestion could be answered; they had done both the complement fixation and the Wassermann tests on some patients. In one case, that of a woman who had been to several dispensaries complaining of pain in her back, and whose condition was not diagnosed, there was a negative Wassermann and a two plus positive tuberculosis complement fixation test. This was a surprise, as the woman showed no symptoms of tuberculosis. The woman was examined with the *x*-ray and it was found that she had a beginning Pott's disease. With reference to the relationship of a positive Wassermann reaction and the tuberculosis complement fixation reaction, he believed a positive Wassermann reaction had nothing to do with the complement fixation reaction for tuberculosis. They had among their employees a number of normal people and in applying the routine Wassermann test to them they had also applied the complement fixation test and had not found one positive reaction. From the laboratory standpoint, Dr. Miller mentioned two points which might be discussed. He said that the technique was the same as that of the Wassermann test. It was too bad that there was no one definite laboratory technique for the Wassermann test. An effort had been made in this city to reach an agreement as to a standard technique, but each man insisted that his method was best and no definite technique had been decided upon. In the complement fixation test for tuberculosis it was absolutely imperative that all workers should follow the same details and not each one go his own way. The complement fixation test for tuberculosis was a very sensitive test and not a rough test like the Wassermann. One must be very careful that the antigen was rubbed up very fine. Then, too, the complement must be titrated, very carefully, and the normal antibodies against sheep's red blood cells must be considered. If a laboratory worker undertook to do this reaction and found that his results did not correspond with those of Dr. Miller he should not blame the reaction but should make an effort to see where his error lay.

Dr. Leo Kessel said he had had the privilege of observing the complement fixation test tried upon a variety of clinical material for almost two years and was convinced of its value in the diagnosis of active tuberculosis. He was interested in seeing whether the intensity of the serum reaction in any way paralleled the clinical activity of the pulmonary process. A group of about seventy patients, all showing tubercle bacilli in their sputum, were arbitrarily divided into four classes, varying in degree of clinical severity from those with no toxic symptoms, no acceleration of pulse, and no fever to those presenting marked toxic symptoms and who, for the most part, were bedridden. Tabulated results were shown by a chart. Within general limits a relationship seemed to exist between the intensity of the serum reaction and the degree of the activity of the tuberculous process exhibited by these patients. Certain discrepancies were pointed out, but in spite of these discrepancies it was evident that the serum reaction bore a direct rather than a haphazard relationship to the intensity of the pulmonary process. Three patients in whom active pulmonary tuberculosis had been diagnosed persistently presented a negative fixation test, and two of these proved ultimately to be pulmonary syphilis, one a bronchiectasis. In a fairly large series of patients with clinical evidence of syphilis the speaker had never seen a complement fixation for tuberculosis positive. He felt that a positive complement fixation for tuberculosis in a patient with a positive Wassermann reaction pointed definitely to an active tuberculous focus.

Dr. Philip Castleman of Boston said that there was very little to add to Dr. Miller's splendid paper, except to say that he had been a little too modest in speaking of his own antigen. In Boston they had tried all the antigens in general use and in their hands none of these antigens had given as good results as had that of Dr. Miller. He had come to the conclusion that the only reliable antigen was the one suggested by Dr. Miller and he was using that antigen at present. Dr. Miller had sent him the organisms for the antigen from his laboratory. Dr. Castleman said he had had quite a little experience because he had endeavored to get the clinicians to allow him the use of their clinical records to compare with the findings of the complement fixation test for tuberculosis on all the specimens that came in for the Wassermann test. He had thus made over 7,000 tests, and out of those 1,358 were positive for the Wassermann reaction. Of these there were 332 patients who gave a positive tuberculosis complement fixation test, and of these 243 gave a negative Wassermann and 89 gave a positive Wassermann. These 89 cases giving both the Wassermann and tuberculosis fixation positive he had endeavored to keep in touch with through the physicians who had sent in the specimens. They had been able to follow up 35 patients, and of these 24 had shown definite signs of tuberculosis. The question, where one found a patient with a posi-

tive tuberculosis complement fixation reaction, was whether he would develop clinical signs of tuberculosis later. As an illustration he cited the case of an Italian woman, 40 years of age, married, who had been complaining of pain in her back for ten months. The patient was cystoscoped and the catheterized specimen of urine was examined and found to be sterile and inoculation into a guinea pig had been negative, giving no evidence of tuberculous infection of the kidney. The complement fixation test for tuberculosis, however, was positive. Six weeks later a guinea pig was inoculated with a specimen of the urine and this time gave a positive result. The woman was operated, the left kidney removed and the pathological examination showed tuberculosis of the kidney. Dr. Castleman cited several other cases in which a positive tuberculosis complement fixation test in a patient showing no symptoms of tuberculosis was found later to have had the disease. Taking all these cases into consideration, he said he felt that the test was absolutely accurate in showing the presence of tuberculosis if it was carried out by skilled laboratory men. There were a few very necessary points to be considered in making the test. First, the blood must be fresh. Often a blood two or three days old became anticomplementary. Second, it was absolutely necessary to fix the complement for forty minutes; often it was better to allow it to stand for one hour before adding the sensitized sheep cells. Third, the reading should not be made before one hour nor should it be made later than two hours after adding the sensitized cells. Fourth, the ice box method took too long; the water bath at 37° C. was entirely satisfactory. As regarded the cross fixation between tuberculosis and syphilis, he endeavored to show that it did not exist and mentioned results of the following experiments: He set up four tubes containing blood which was previously found positive for both the Wassermann test and the tuberculosis test. Tubes 1 and 2 were tested by the Wassermann test and tubes 3 and 4 by the tuberculosis complement fixation test. After the completion of the reaction the solutions were filtered. The filtrate from tube 1 was again tested by the Wassermann test and the one from tube 2 for tuberculosis; one from tube 3 for tuberculosis and the one from tube 4 for the Wassermann test. By regulating the volume of the patient's blood he found in a number of cases that the filtrate of tube 1 was negative for the Wassermann, that of tube 2 positive for tuberculosis, that of tube 3 negative for tuberculosis, and that of tube 4 positive by the Wassermann test, thus proving conclusively the absence of cross fixation. He had, however, urged others to carry on this work and report their results, as his work in this line was limited.

Dr. MILLER, in closing the discussion, said that he thought that a few observers were agreed in the belief that there was no cross fixation between luetic and tuberculous sera. He had tested a large number of syphilitic sera, and they were all negative except four; in these four instances he knew nothing of the clinical symptoms at the time of the examination, but it was learned later that there was tuberculosis present in two of these cases; in the other two the disease could not be excluded. Dr. Castleman's work in filtering out the specific antigens and testing the filtrates was very much in line with the work of Bronfenbrenner, who had been able to satisfy himself and others that the antibody for tuberculosis was distinct and separable from the antibody found in luetic serum. Many workers obtained cross fixation because they used antigen which could give lipoidal fixation. In order to determine the effect of injections of tuberculin on the complement fixation reaction, Dr. Miller had injected animals with tuberculin. In animals thus injected he had been unable to get a positive complement fixation reaction and he was inclined to believe that the injection of tuberculin would not produce a positive reaction in normal animals. He was, at present, carrying on experiments to determine the effect of subcutaneous injections of tuberculin on the complement fixation reaction in arrested and doubtful cases. Dr. Miller said the important point to be stressed was that the complement fixation reaction for tuberculosis was a biological and not a mathematical test. In general the reaction paralleled the course and intensity of the clinical picture. Not infrequently it proved of help in diagnosing tuberculosis when the clinician could reach no definite conclusion.

Therapeutic Hints.

Disorders of Dentition.—Whitla uses the following formula when restlessness, sleeplessness, vomiting, and other disturbing symptoms, are present in this period:

℞ Sodii bromidi .....gr. xxxij
Chloral hydratis .....gr. iv
Liquor. ammon. acet.....℥iv
Syrupi simplicis .....℥iv
Aquæ chloroformi.....ad ℥ij
M. et ft. mistura.

Sig.—A teaspoonful every two hours until relieved, for a child 12 months old.—*Dictionary of Treatment.*

Acute and Chronic Catarrhal Conjunctivitis.—May uses iced compresses over the diseased eye for fifteen minutes to an hour, three times daily. The conjunctival sac is also irrigated three or four times during the twenty-four hours with a solution of boric acid or a 1 in 6000 solution of mercury bichloride. A bland ointment (vaseline or boric acid) is to be placed on the edges of the lids at night in order to prevent them from sticking together. A 25 per cent. solution of argyrol or a 5 per cent. solution of protargol should be instilled into the conjunctival cul-de-sac for five minutes from three to six times a day. The lids should be kept closed and each time the eye should be irrigated afterward with the boric acid solution.

The last mentioned treatment should be kept up until the discharge has disappeared. If the disease shows a tendency to become chronic, weak astringent solutions are to be used, zinc, borax, alum, tannic acid, silver nitrate, gr. 1 10 to ℥j; also ointments of the yellow oxide and ammoniated mercury, or silver nitrate 1 per cent., should be applied on the everted lids once a week. The occasional use of the alum or sulphate of copper stick on the everted lids will also hasten recovery. Bland ointments to the edges of the lids at night must be continually applied. As in all chronic catarrhal conditions, the remedies should not be too long continued, but should be changed from time to time.—*Diseases of the Eye.*

Chronic Nasal Catarrh.—Scott recommends the following combination of Sajous for this condition:

℞ Sodii bicarb.,
Sodii bibor.....āā gr. viij 0.5 gm.
Fluidextract. pinus canad..ɱxv 1.0 c.c.
Glycerini .....f℥ij 8.0 c.c.
Aquæ.....q.s. ad. f℥iv 120.0 c.c.

THE DIAGNOSIS AND TREATMENT OF PATHOLOGICAL CONDITIONS IN THE ANTERIOR URETHRA THROUGH THE URETHROSCOPE.

BY MAX HÜHNER, M.D.,

NEW YORK.

CHIEF OF CLINIC, GENITO-URINARY DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE; MEMBER, AMERICAN UROLOGICAL ASSOCIATION, ETC.

IN the following pages I shall discuss at some length and with extreme detail the use of the urethroscope in pathological conditions of the anterior urethra, and will reserve for a future paper, a discussion of the pathology of the posterior urethra as viewed and treated through the posterior urethroscope.

The time is passed, I hope, where a persistent gonorrheal discharge is treated by trying one injection after another, without any concern as to the pathological condition of the urethra which keeps up the discharge.

Of late, much attention has been paid, and rightly so, to the prostate, the seminal vesicles, and the posterior urethra as sources of reinfection in gonorrhea, and the cause of the chronicity of the disease. While recognizing the importance of these parts, however, we must not neglect a careful inspection of the anterior urethra, which may show lesions quite as important as in the parts just mentioned. Lesions in the anterior urethra, moreover, have the advantage over those in the prostate and seminal vesicles, in that they can be brought directly into view and can be directly treated.

It should be borne in mind, also, that there are pathological conditions in the urethra which can be diagnosed and treated in no other way than by the use of the urethroscope. Moreover, it cannot be impressed too emphatically upon the reader, that, in the majority of cases, the most obstinate gonorrheal stricture of the urethra was at first a mere infiltration in its walls, which could easily have been seen and successfully treated if the urethroscope had been employed at the right time, or as a matter of routine in the treatment and diagnosis of urethritis. I must emphasize that the *only* way to diagnose a stricture of the anterior urethra before it has advanced so far as to give obstructive symptoms is by the timely employment of this instrument; and, as a corollary to the above, I would say that a stricture of the urethra following a gonorrhea ought to be diagnosed and treated before any symptoms of it are present.

The present paper is the result of many years' experience in urethroscopy, and the author has employed practically every form of instrument that is on the market. He has also kept in close touch with the literature on the subject, both here and abroad, but still has no hesitancy in stating that there are certain technical details and certain "tricks" described in the following pages which cannot be found elsewhere.

It is the object of this paper to present a *practical* discussion of the subject, not omitting the minutest detail, so that any one who is willing to devote his time to the subject can with a little patience master it. He can then treat his gonorrheic patient with intelligence and obtain results which cannot be obtained by any other method.

The entire subject will be discussed under the following captions:

1. Description of instrument.
2. Precautions and contraindications in the performance of urethroscopy.
3. Preparation of instruments and patient.
4. Appearance of the normal urethra through the urethroscope.
5. Pathological conditions in the anterior urethra seen through the urethroscope.
6. Treatment of pathological conditions through the urethroscope.

1. *Description of Instrument.*—It is important to have an instrument with a magnifying lens placed at the right focal distance. The lens should be so arranged that it can be moved from side to side, so that intraurethral applications can be made with the lens *in situ*. With this arrangement we have the magnified picture of the urethra directly under vision while making such applications. I would especially caution against buying instruments without a magnifying lens attachment. Ingenious instrument dealers will at times try to persuade you to buy such instruments on the plea that one sees the urethra in its natural condition, and not in an artificial condition of magnification. One could, for the same reason, refuse to employ the microscope for the examination of a pathological specimen and expect to gain more knowledge by looking at it with the plain eyes "in its natural condition." For many years I employed a urethroscope without lens attachment, and while I could recognize gross lesions it was impossible to make out the finer pathological changes which characterize the very beginning of the change from normal to pathological, and which it is so very important to recognize at the earliest possible moment. While in Europe I spoke with Wossidlo[3] on this very point, and he took exactly the same view of the subject as I do. It is also essential that the lens should not be too small, as is the case with some of the urethroscopes on the

market. The best lens is about ½ inch in diameter, and arranged on a pivot, so that it can be swung from side to side or entirely away from the opening if necessary. (See Fig. 1.)

One urologist, thinking that a large size lens

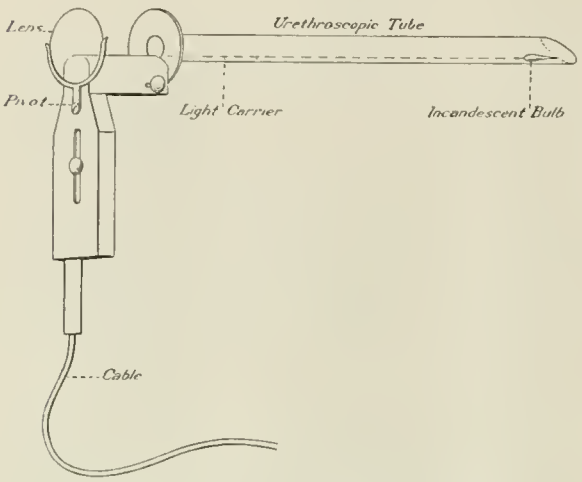

Fig. 1.—Urethroscope with lens attachment.

would be in the way while making applications to the urethra directly under vision, invented a urethroscope in which the lens is very small, so that an applicator (or other instrument) can be put into the urethroscopic tube while the lens is in position. The trouble with such a small lens is that it does not give nearly as much magnification as the larger one does, as one can easily convince himself by comparing the two. Later on, in describing the technique of urethroscopy, I shall show that the larger lens need not at all be in the way of making direct applications or doing operations in the urethra directly under vision with the lens in situ. If one has already purchased such a urethroscope it is an easy thing to have the small lens removed and the larger one put in its place.

In the urethroscope pictured above it will be noticed that the source of illumination is a small electric lamp attached to a light carrier which is inserted into the lumen of the urethroscopic tube when in use. It is true that the light carrier takes up a certain amount of space in the lumen of the tube, thus giving less room for intraurethral manipulations, but after some experience in intraurethral work we will find that there is plenty of room left to do all the manipulations necessary. In order to avoid the employment of a light carrier, several urologists have invented urethroscopes with a lens system so arranged that the source of light is at the proximal end of the tube (near the eye of the observer) and is focused into the distal end by the system of lenses. This arrangement leaves the entire lumen of the tube free for work. I would especially caution *against* the use of such urethroscopes. While theoretically correct, practically they are of very little value. If you look through one of them, all you see is a great flood of light at the distal end of the tube, and while very *gross* pathological lesions can be made out, it is impossible to make out the important finer details. It might sound peculiar, but it is nevertheless a fact, that light is more or less opaque, and you cannot see nearly as clearly through a flood of light that has been focused from a distance of a few inches as when the source of light is only one-quarter inch away from the object. Do not let the dealer mislead you by having you look through the instrument held against your hand to show you how brilliant the light is at the other end. As before said, you see plenty of light, but nothing else.

2. *Precautions and Contraindications in the Performance of Urethroscopy.*—1. Never use the urethroscope in the presence of a marked purulent urethral discharge, or an acutely inflamed urethra, whether either condition is due to gonorrhea or not. If, however, the acute stage has long since passed, and there remains a persistent urethral discharge, such discharge is no contraindication to the performing of urethroscopy. On the contrary, it is often to the credit of the urethroscope that the cause of such persistent discharge can be determined by no other means. Even though the discharge contains a few gonococci (not many, of course), there would be no objection to urethroscopy, as here again a small infected follicle may be discovered and treated through the urethroscope, which follicle may be the only reason for the persistence of the gonococci.

2. Never pass instruments into the urethra just prior to making a urethroscopic examination, as artificial hyperemia, erosions, or other artificial conditions, may be produced. If you want to make a complete examination at one sitting, do the urethroscopy first, then explore the urethra with bougies à boule, sounds, or any other instrument.

3. Except in unusual cases, do not attempt to make a urethroscopic examination in the presence of a very small meatus. Even if you can insert a very small tube, the area of vision through such a

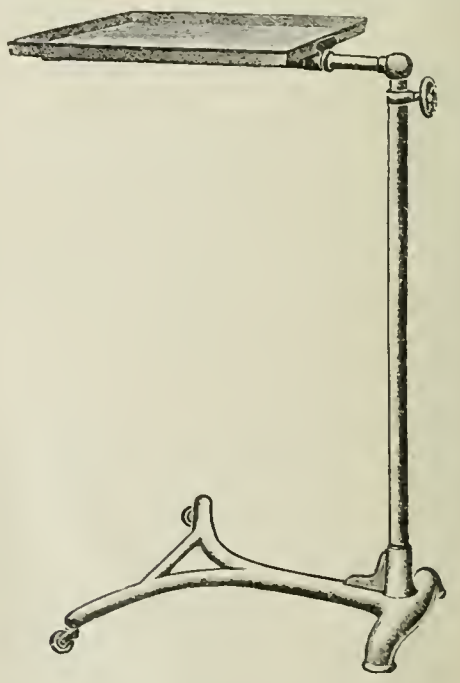

Fig. 2.—Table for urethroscopic instruments.

tube is so small that you cannot see nearly as much or as well as when a larger tube is employed. If possible, do a meatotomy, and then employ a larger tube.

4. Do not use a tube so large as to stretch the

urethra abnormally, because the pressure of the tube will cause artificial anemia and otherwise distort the parts. In many textbooks the advice is given to use the largest tube that it is possible to get into the urethra. This advice is bad, for the reasons above given.

5. It is not advisable to perform anterior urethroscopy and posterior urethroscopy (or cystoscopy) at the same sitting. The irritation of so much instrumentation is harmful to the average urethra, and the pain of the two proceedings is more than most patients can endure. In exceptional cases, where patients come from out of town, and whose stay in the city is limited, if it becomes necessary to perform both examinations, do the anterior urethroscopy first.

6. Never use cocaine or other anesthetic for the performance of anterior urethroscopy, as the action of the drug may prevent a clear, natural impression of the parts.

III. Preparation of Instruments and Patient.—Before commencing, we should have everything in readiness for diagnosis and *treatment*. We must remember that a lesion discovered during examination may be very difficult to locate and find at a subsequent examination. It is advisable, therefore, if at all possible, to be prepared to treat it at once while we have it under vision.

We should have ready the following appliances: (1) Urethroscopic tubes with obturators, (2) light carrier, (3) cotton applicators, (4) intraurethral forceps; (5) solutions of silver nitrate, or applicators which have been dipped in such solutions, or pure silver nitrate which has been fused upon a stick or applicator; (6) for special operations we might need cautery knife, electrolysis needle, and other intraurethral operating instruments. Most of these latter instruments need only be prepared for subsequent examinations, as such operations are not generally done at the first sitting. They will be described later on.

The urethroscopy may be performed with the patient lying flat upon his back, or in the cystoscopy position. I personally find it more convenient and less tiresome to the patient to have him flat upon his back. This position has also the advantage that the urethroscopy may be followed, if necessary, by exploration of the urethra with sounds, bougies à boule, or other instruments, without changing the position of the patient. A convenient method is to have a table (Fig. 2) like an invalid table, which can be raised and lowered, across the lower portion of the patient's legs and knees, upon which are placed, upon a sterile towel, all the articles above enumerated.

I shall now describe the above appliances in detail:

1. *The Urethroscopic Tubes and Obturators.*—These come in various sizes, corresponding in number to the ordinary urethral sounds. It is not at all necessary to have many sizes, for practically all the work may be done with four different sized tubes, as follows: 20 F., 24 F., 27 F., and 31 F. Some of the tubes have the distal ends circular, while some are oval. It makes absolutely no difference which is used.

2. *The Light Carrier.*—This consists of a small metal rod with a minute incandescent lamp at its end. Wappler has recently made his light carriers so that the lamps can be simply screwed on to the metal rod. This is a great improvement over his previous models, in which a fine piece of wire had to be fed through the narrow lumen of the metal rod. The light carrier has a magnifying lens attached to it, and so arranged that the lens can be turned from side to side, so that intraurethral applications and operations can be performed.

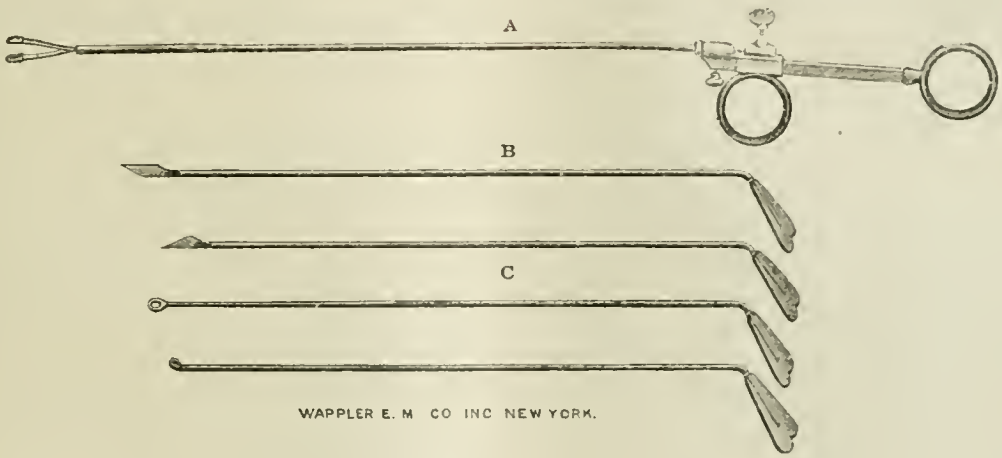

Fig. 3.—Urethroscopic Instruments. A, forceps; B, knives; C, curettes.

3. *The Cotton Applicators.*—These come in two sizes. Those for the anterior urethra are about 6 inches in length, and those for the posterior urethra are about double this length. They are made by dipping the ends of the wooden sticks in either water or collodion and wrapping cotton around them while wet. The long ones used for the posterior urethra may have cotton wrapped about both ends. There is less danger of the cotton coming off if collodion has been used. After having been made up in quantity they may be sterilized by using any form of dry-heat-pressure sterilizer. The sterilization does not affect the collodion.

We should have these applicators made up in two different styles, one for mopping the urethra and the other for the application of medicaments to the urethra. Those used for mopping away the blood or mucus from the urethra should have much more cotton wrapped about them than the others. In fact,

those used for applying medicaments should have merely the minutest amount of cotton on them; just enough to hold a small amount of the medicine. Those used for mopping should not have so much cotton about them as to interfere with their *easy*

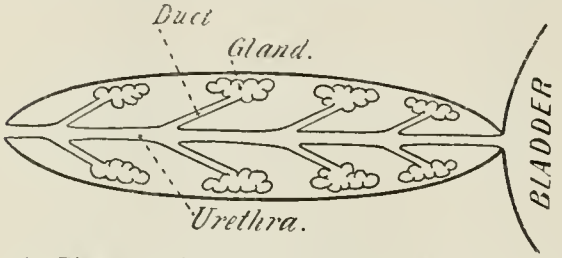

FIG. 4.—Diagrammatic scheme of the glands and ducts of the anterior urethra.

passage through the urethroscopic tube. If you do much urethroscopy it is advisable to have two kinds of applicators for mopping, one for the smaller size tubes and the other for the larger tubes. In making up the applicators it is always advisable to have too little rather than too much cotton on them, as they become much thicker with time, probably through the absorption of moisture. The final test is their ability to go *easily* through the urethroscopic tube.

4. *The Intraurethral Forceps.*—(Fig. 3, A.) This is a great convenience, though not of absolute necessity in urethroscopy. It sometimes happens that some of the cotton comes off the applicator and remains in the lumen of the urethroscopic tube, or even in the urethra, just beyond the tube. This accident may result either from having the cotton carelessly wrapped on the stick, or by forcing an applicator with too much cotton on it through a urethroscopic tube too narrow for that particular applicator. With this forceps it is surprising to see how easily the cotton can be removed from the tube or urethra. One may try the experiment by packing a urethroscopic tube as tightly as possible with cotton, and then appreciate how easily this can be removed with the forceps.

In case one does not possess such a forceps, and a piece of cotton becomes dislodged in the tube, it may be removed by introducing a plain applicator stick, without cotton, but wet at the end, and by a twisting motion engage the piece of cotton and remove it. It may take a little time, and cause some embarrassment in the urethroscopic examination, but with patience you can always get it out. Even if the piece of cotton has been pushed out of the end of the urethroscope into the urethra proper, it generally can be removed. Should it remain in the urethra, however, it will cause no trouble, as the force of the urine will certainly carry it out. This, however, ought never to happen. The urethral forceps can also be used to remove stones which have been stuck in the urethra.

5. *Solutions for Medicating the Urethra.*—As previously stated, the applicators which are to carry the solutions should have only a minute amount of cotton on them. It is advisable to dip the applicators into the solutions beforehand and shake off the excess, and so have them ready for use. The reason for this is, in the first place, that by so doing there is less danger of having too much solution on them, for it is not advisable to have them soaking wet; and in the second place, as before explained, when we discover a lesion in the urethra we must immediately go for it, for unless one has an assistant the mere act of dipping the applicator into the solution and shaking off the excess is enough to dislodge the instrument from the lesion. These may be trifling facts, but in actual experience they are of importance.

The solutions of silver nitrate generally employed are 10, 25, and 50 per cent., and the pure caustic. The first three are prepared by simply putting the cotton-covered applicator into the respective solutions and shaking off the excess. The pure silver stick consists simply of some pure lunar caustic fused on the end of a wooden applicator, or at the end of a fine metal probe. The latter is essential for getting into the minute ducts, while the former may be used if a larger surface is to be treated. The wooden applicators are generally too thick for ducts or follicles.

The metal applicators which carry the pure caustics are made by heating the end of the applicator, and, while hot, putting it against a small crystal of silver nitrate. The crystal will adhere to the end of the probe, which is then carefully heated further in an alcohol lamp or bunsen burner until the silver liquefies around it evenly, when it is permitted to cool. It is well to have the solution run toward the point, so as to have a minute knob at the end when it has cooled. It is important to use only the minutest crystal of silver nitrate, or else the applicator end will be too thick to enter the minute follicle opening.

The wooden silver-nitrate applicators may be bought ready made, but are somewhat expensive. With a little experience, they may be made by the doctor himself. Take a molded silver-nitrate cone, place it into a small test tube, and heat it carefully in the test tube till it melts. While it is melted dip the wooden applicators in, holding them downward, so that the solution flows toward the end of the stick. The trick in the making is not to dip the wood in while the solution is too hot, or else the end of the applicator will be burned off. It is likely that the first few attempts will fail, but after a little experience we get the right moment when to dip

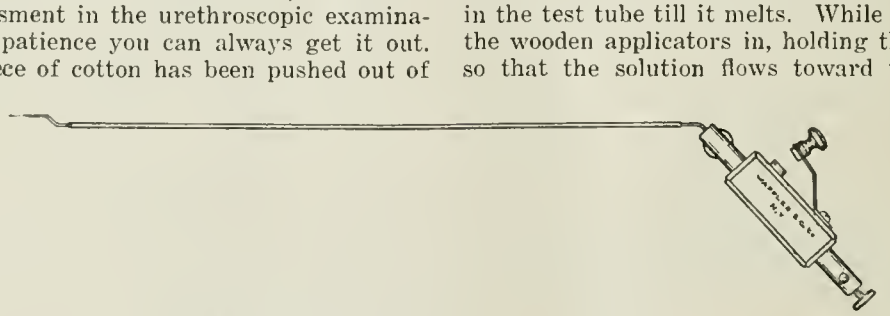

FIG. 5.—Electrolytic needle for urethroscopic use.

the wood in. If the silver at the bottom of the test tube has cooled and become hard, it may be reheated again and again as long as there is the smallest portion of silver nitrate left. These home-made applicators may not look as nice as those bought, but for practical use they are just as good.

IV. Appearance of the Normal Urethra Through the Urethroscope. Method of Performing Anterior Urethroscopy.—The urethroscopic tubes and their obturators are sterilized by boiling, and kept in an antiseptic solution. The light carrier, with lamp, is simply washed with alcohol and kept in the same solution or on a dry, sterile towel. The lamp is tested, and the proper degree of illumination obtained; the current is then temporarily turned off. It is best not to test the light before the patient, as it may make him very apprehensive to think that a red-hot lamp is going to be inserted into his urethra. Everything that might be used is now placed in readiness on a table covered with a sterile towel. One should be certain to have very many applicators, as in some cases there is more mucus and more oozing than is expected.

The patient is examined lying flat upon his back. The penis is cleansed with soap and water, alcohol, and weak oxycyanide of mercury solution (1:4000). A sterile towel with a hole in the center for the penis is now applied over the patient, so that the penis projects through the hole and lies on the sterile towel. The instrument table may be spread over the lower portion of the patient's legs and knees. The source of light may be either the ordinary dry-cell battery, or the street current with an intervening rheostat.

The examiner should also sterilize his hands or use sterile gloves. The proper size tube is taken from the solution, and the excess of solution allowed to flow off. If the obturator is in the sheath of the urethroscopic tube, it should first be removed, as the tube will be found to be filled with solution. The drier the instrument is, the less mopping will have to be done later on, when the instrument is in situ. For this reason also we should employ as little lubrication as possible.

If the distal end of the urethroscopic tube is round, we may introduce it in any way; but if oval, we introduce it so that the oval opening looks upward; *i.e.* toward the roof of the urethra. After the urethroscopic tube has been introduced we remove the obturator and mop out the urethra until it is perfectly dry. We then introduce the light carrier, the lamp of which has been previously tested and the proper illumination procured. As soon as the lamp is in situ we turn on the current. Every light carrier has an arrangement whereby the current may be turned either on or off by a switch attached to the handle of the carrier. We then turn the lens so that we may look through it.

We then look in, and no matter what portion of the urethral mucous membrane comes into view we so manipulate the tube that the central opening comes into view. This central opening of the urethra is always our landmark, from which we get our bearings and know where we are. No matter what portion of the urethra we examine, we should always come back to this central opening before we explore a different portion of the urethra.

The central opening is the lumen of the urethra. Normally, except during micturition or ejaculation, there is no lumen to the urethra. The walls are always in contact, and the urethral mucous membrane is thrown into folds to allow of its distensibility during coitus. And so, when we look through the urethroscope, which artificially opens the urethra, we see an indication of an opening from which radiate 18 or 20 fine lines. These fine lines represent the folds of the urethral mucous membrane, and the indication of the opening, which is known as the central opening, represents the closed lumen of the urethra. While this picture may vary slightly according to what portion of the anterior urethra is inspected, and may also vary somewhat in different individuals, the main picture must be the same for a normal urethra. We must have a closed, or very slightly opened canal, and we must have the fine radiating lines above described. Any variation from this shows a loss of elasticity in the urethral walls, which means the commencement of stricture formation. The only exception to this rule is the urethroscopic picture of that portion of the urethra just beyond the meatus. In this portion there are normally no folds, the mucous membrane is not elastic, and we see a more or less wide-open central figure, with hardly any radiating lines. In other words, the urethroscopic picture which is absolutely normal for the region near the meatus would be considered pathological if seen anywhere else in the anterior urethra.

Inasmuch as it is the object of this article to give a *practical* description of the parts, a description which will be of definite use to the worker in urethroscopy, I will not burden these pages with a description of the many varieties of pictures that may be seen in the normal urethra, but will only emphasize the important point already referred to, that as long as we have *a closed or slightly opened central figure with distinct radiating lines we have a normal condition of elasticity of the urethra, and any variation from this is pathological, the region near the meatus excepted.* We thus see that there is nothing difficult or mysterious in the comprehension of the urethroscopic picture of the normal urethra, but it is just what we would expect from the anatomy of the parts. The color of the normal mucous membrane of the anterior urethra is of a reddish hue, and has a glistening appearance. Neither the color nor the glistening can be described in words, nor even reproduced well in colors, for which reason no colored plates are presented here. It must be seen in order to be recognized. Where the urethroscope presses upon the mucous membrane a temporary local anemia is sometimes produced, and as the pressure is removed by moving the urethroscope the blood may be seen to rush into the parts. All this is strictly normal. Any other change is abnormal. Small spots of intense redness denote erosions ;or, if around the urethral opening of a follicle, it generally means infection of the follicle. A loss of the glistening appearance is aften the first stage of infiltration of the submucous tissue, and often indicates a beginning stricture. A white or grayish appearance without any blood-vessels indicates the scar tissue of permanent stricture. All these appearances will be gone into in detail when discussing the pathological appearances of the anterior urethra. All we have

to remember for the present is *that a mucous membrane with glistening appearance and of reddish hue is normal, and any variation therefrom abnormal.*

Having observed the appearance of the mucous membrane, as regards the central figure, striations, color, and glistening, we now observe the condition of the follicle openings. As most of these are situated in the upper wall of the urethra we so manipulate the urethroscope as to bring this portion into view. Normally, the follicle openings cannot be seen at all, or appear merely as small or medium-sized holes in the mucous membrane. Any variation from this is abnormal. Openings with pus or secretions oozing out of them indicate infection (not necessarily gonorrheal), and openings which are red and inflamed, or surrounded with a halo of redness, show inflammation of the follicle, and, most likely, infection.

After studying one particular area of mucous membrane we slowly move the urethroscope toward the meatus, looking in all the time, and noting any pathological lesion that may appear. We examine the urethra from behind forward; that is, as we are removing the instrument. We must not neglect to look at the mucous membrane at the very tip of the penis, that is, just near the meatus. Should there be any bleeding or mucous in the way, we remove the light carrier and mop the parts dry. Of course, it is possible to dry the parts with the light carrier in situ, but I have found it more convenient to remove the light carrier.

V. Pathological Conditions of the Anterior Urethra as Seen Through the Urethroscope.—The most frequent pathological conditions found in the anterior urethra are: (*a*) New growths, (*b*) granulations and erosions of the mucous membrane, (*c*) infections and inflammation of the follicles and glands, (*d*) infiltration of the submucous tissues, forming the different grades of stricture formation.

A. *New Growths.*—These are rather rare, and are easily recognized. I have seen only two or three cysts of the anterior urethra, and do not believe that I have seen more than a score of cases of warts in many hundred urethroscopies. I have not kept statistics, but such is my general impression.

Cysts in the anterior urethra are exceedingly rare. In the posterior urethra, especially in the region of the verumontanum, they are much more common. In one of the cases where I found a cyst in the anterior urethra the patient had his first gonorrhea, but in spite of persistent treatment it refused to get well. As a matter of fact, treatment seemed to make absolutely no impression upon the disease. The pus came out just as profusely, and the gonococci were just as numerous after several weeks of treatment as on his initial visit. Contrary to the general rule that a urethroscopy should not be performed in the presence of an acute discharge, I felt that there must be something in the urethra to account for this lack of response to treatment. I therefore urethroscoped him, after carefully washing out the urethra, and followed the urethroscopy with an intravesical irrigation. No harm resulted from the urethroscopy. At about two inches from the meatus I found a large urethral cyst which almost completely filled that portion of the urethra. This cyst formed a mechanical hindrance to the injection fluid which the patient used, although there was no interference with the urinary flow, possibly due to the powerful muscular action of the bladder. On the surface of the cyst were many fine blood-vessels. I do not know if the cyst was congenital or acquired, as the patient never had had a urethroscopy performed on him previous to his present infection. Removal of the cyst caused the gonorrhea to yield rapidly to treatment.

As a matter of diagnosis, we should remember that sometimes prolonged pressure of the urethroscopic tube at one point may cause a temporary edema in a localized spot a little removed from the point of pressure, and this edema may be mistaken for a cyst by an inexperienced observer. If we watch such a supposed cyst for a little while, we will see it completely disappear as the circulation is reestablished.

Polypi are also at times found in the anterior urethra.

Urethral warts are generally multiple, and cannot be mistaken for anything else. They are perfectly benign neoplasms, and have not the tendency to degenerate into malignant tumors which is so characteristic of vesical papilloma. As a matter of symptomatology, whenever a person suffers from excessive hemorrhage from the urethra after the passage of a sound we should suspect warts, either in the anterior or posterior urethra. In some cases the hemorrhage is very persistent and even alarming, and may continue for several days. Even after the hemorrhage has stopped, the most gentle urethral instrumentation may bring it on again. During the period of hemorrhage it is not advisable to do any instrumentation, but a retained catheter may be left in the bladder until all signs of hemorrhage have ceased. We then do nothing for several weeks, after which time, having everything in readiness to check a possible return of the hemorrhage, we attempt to remove the warts rapidly from either the anterior or posterior urethra.

The importance of the suspicion of warts in cases of urethral hemorrhage cannot be too strongly emphasized. I have seen one case in which, although the patient was in a large general hospital, the diagnosis was not made, and the patient had submitted to two perineal external urethrotomies for supposed stricture without relief. After his discharge from the hospital he was referred to my dispensary clinic, and a simple anterior urethroscopy revealed the entire anterior urethra studded with warts; and later a posterior urethroscopy showed the same condition to exist in the posterior urethra. Treatment brought about a complete cure.

Carcinoma of the urethra is very rare. Oberlander[3] has seen only three cases of it in 40 years. He has also never seen a case of true tuberculosis of the anterior urethra.

Chancre of the urethra is not so rare, but it is generally situated right near the meatus, and we rarely need a urethroscopic examination for its detection.

B. *Granulations and Erosions of the Urethral Mucous Membrane.*—These are frequently found by the beginner in urethroscopy, but really occur very seldom in the *anterior* urethra. Of course, if we explore the urethra with several bougies à boule,

sounds, etc., and do a urethroscopy immediately afterward, we will find many erosions, but these are merely the artificial product of the explorations. I have, therefore, purposely emphasized the caution either to make explorations and urethroscopy at different sittings, or, if they are to be done at the same sitting, to do the urethroscopy first. Granulations, while not uncommon in the posterior urethra, are not nearly so common in the anterior urethra. They are more often found by beginners, who view the urethra through a urethroscope without a magnifying lens. Erosions cannot be mistaken for anything else. They are simply slight denudations of the superficial layers of the urethral mucous membrane and bleed at the slight touch.

C. *Infections and Inflammations of the Follicles and Glands.*—I have put these two conditions together, because they are generally found together. An infected follicle duct opening is generally inflamed, and similarly, in the vast majority of cases when we see the mouth of a follicle duct inflamed, the inflammation is due to infection in the follicle, although, for scientific proof, we most resort to bacteriological examination. Except in cases so far advanced that the follicle is so distended with pus that it can be palpated from the outside, the *only* way we can diagnose an infected follicle duct or gland is by the use of the urethroscope. An inflamed follicle opening appears in the urethroscope as a more or less prominent hole or slit, intensely red, and often surrounded by a halo of redness. It should be remembered that normally the follicle openings are either not visible at all, or only faintly so, so that, when a follicle opening stands out prominently, and is of a bright red hue, it is inflamed, and the inflammation is generally due to infection.

An infected follicle appears as a more or less prominent opening from which pus is seen oozing. As a general thing, it is also surrounded by a halo of redness, but not necessarily so. One must be careful, however, to have the field perfectly dry, so as not to mistake lubrication for pus.

Those that decry the use of the urethroscope, and see no advantage in it, should see some of these infected follicles, and appreciate how, without such information, they must grope in the dark, searching for the cause of the persistence of a gonorrheal discharge, and, what is still more important, they will then appreciate how such a follicle can be treated, and the cause of such discharge eliminated by this means. Such treatment cannot at all be applied in any other way than by the use of the urethroscope.

In his article on "Urethroscopy and Marriage Consent" Asch[3] cites several cases of patients without any symptom of an uncured gonorrhea, in which no gonococci were found either on smear or culture, and no flocculi were found in the urine, in whom, however, the urethroscopic examination revealed small follicular abscesses in the urethra, the puncture of which through the urethroscope brought out pus containing virulent gonococci. Other pathological conditions, such as membrane formations under which gonococci were still present, were found. In all of these cases, the gonorrhea had long since ceased giving any symptoms, and the patients only came to be examined for prospective wedlock—more as a matter of routine and conscience.

D. *Infiltration of the Submucous Tissue, Causing the Different Grades of Stricture Formation.*—These infiltrations are of exceeding importance, as the forerunner of possible stricture. *One must not wait till signs of obstruction appear before diagnosing a stricture of the urethra, but must make the diagnosis by the urethroscopic picture,* before any signs of obstruction appear, and before it can be appreciated with the bougie à boule.

I have said that the urethroscopic picture of the normal urethra shows a central opening from which radiate between 15 and 20 fine lines which represent the folds in which the mucous membrane is thrown. In a practical treatise like the present it is unnecessary to discuss the various theories of stricture formation or even to go into much detail as regards the pathology of strictures. Suffice it to say that at the commencement there is a subepithelial deposit of small round cells at one small area; this is called a soft infiltration. Through the urethroscope we notice a disappearance of some if not all of these fine radiating lines at this point. *This is the first stage of stricture formation,* and it is exceedingly important to diagnose this condition, as at this stage the infiltration is still soft, and proper treatment will restore the urethra to an absolutely normal condition. The disappearance of the fine lines means a loss of elasticity at this area due to the deposit of the small round cells. The mucous membrane will also have lost some of its luster. At this stage of stricture formation, no scar tissue having yet been formed, no indication of this earliest stage of pathological change in the urethra can be appreciated with either the bougie à boule, sound, or any other instrument. The importance of urethroscopy at this stage will be seen, *as it is the only way to diagnose this condition.* A failure to diagnose and properly treat the urethra at this stage may let the golden opportunity slip by, and the condition may develop into a true stricture.

Should no treatment or improper treatment be instituted, however, the pathological processes will continue, and the next stage will set in. This is characterized by the organization of these cells, and the development of bundles of connective tissue in the deposit of small round cells that constituted the previous soft infiltration, with finally the formation of true scar tissue just as in any other part of the body. This is called a hard infiltration. When this has taken place a restitutio ad integrum is no longer possible. At this stage, moreover, a careful examination with the bougie à boule may detect a beginning thickening at this point, or even a beginning constriction. The urethroscopic picture now shows a disappearance of all the fine lines, meaning a loss of the elasticity of the urethra at this point, and we may even recognize scar tissue as clearly and distinctly as in any other part of the body.

If the pathological process continues, we will finally see distinct scar tissue, a loss of the fine lines not only at the point of stricture but for some distance in the urethra at either side of it, and a canalization of the urethra in this area. By this latter term is meant that the urethra no longer closes up beyond the end of the urethroscopic tube as the tube is withdrawn, but on account of the rigidity of the scar tissue it remains wide open so that we can actually look into the urethra beyond the limits of the urethroscopic tube. The Germans

well express this, by saying that the picture gives one the impression as if looking into the mouth of a cannon. One sees a distinct inelastic canal instead of a soft, closing urethra as the urethroscope is being withdrawn.

As stated before, however, as we approach the region toward the meatus, the fine striations are *normally* absent, and this must not be interpreted as scar tissue. The above description of the pathological formation of stricture applies to every part of the anterior urethra except that portion near the meatus.

Before closing this description of the urethroscopic picture of pathological conditions in the anterior urethra, I would like to record a very rare condition, which I have encountered only once in all my experience, but which it is very important to recognize.

For want of a better name, I have called it membranous urethritis following gonorrhea. This condition has been very seldom described, and even some of our larger textbooks devoted to urology, make absolutely no mention of it. Asch,[2] however, describes a somewhat similar condition under the title of mebranous formation. The disease is very difficult to cure and is the cause of the persistence of the gonococcus for indefinite periods of time, but with very little urethral discharge. I do not think it can be cured except by treatment through the urethroscope, and it certainly cannot be diagnosed without resorting to urethroscopy, as it presents no symptoms, except a very scanty urethral discharge with the persistence of gonococci for months—a symptomatology which may be due to very many other conditions.

The urethroscopic picture, however, is very characteristic. One sees a dirty grayish membrane covering the mucous membrane of the urethra. Sometimes the membrane covers large areas, and sometimes it is only seen in patches. It is very easily removable in parts, and the mere introduction of the urethroscope causes pieces of various sizes to separate. One often sees the small detached particles rolled up in clumps in various parts of the urethra, looking not unlike the particles which one encounters in infants upon retracting an adherent prepuce. I believe that the small particles encountered are caused by the breaking up of the larger patches either by the urethroscope or by the urinary stream. It seems that the gonococci flourish luxuriantly beneath the membrane, and are unaffected by any irrigation fluid, and this is the cause of their marked persistence. The treatment will be given later under the proper caption.

In the above description of the pathological conditions encountered in the anterior urethra with the aid of the urethroscope, I have strictly adhered to my intention to make it as *practical* as possible. I have, therefore, purposely omitted the description of rare or unusual findings, such as cases of primary carcinoma or tuberculosis of the urethra, which are at times reported as medical curiosities. If we consult the vast and exhaustive German literature on urethroscopy we shall find a great array of pathological conditions described and classified as seen in the anterior urethra. Conditions are described as psoriasis of the urethral mucous membrane, eczema of the urethra, etc. Now, I have no quarrel with these authors, and admire their thoroughness and deep study of the subject. Of course, we find unlimited variations and combinations of conditions in the urethra just as in any other mucous membrane, but to give each shade of differentiation a different name, as some of the European authorities have done, is to my mind intensely impractical. It has, moreover, absolutely no bearing upon the treatment or cure of chronic gonorrhea or any of its sequelæ. It is for this reason that I have described only those conditions which one is apt to meet and which have a bearing upon the diagnosis and treatment of gonorrhea.

VI. *Treatment of Pathological Conditions Through the Urethroscope.*—Under this caption I will only describe the urethroscopic treatment of urethral lesions. Obviously certain conditions diagnosed by the use of the urethroscope such as strictures, require treatment other than urethroscopic, such as dilatations with the Kollmann dilator, treatment by sounds, etc., but description of such treatment is not within the province of this paper. I will only describe such treatment as can be given through the urethroscope and how the treatment is applied.

One of the most frequent conditions encountered is the presence of infected follicles in the urethra. As previously stated, these are more often found on the upper wall of the urethra. They are often the cause of the chronicity of gonorrhea, as well as of the frequent relapses and reinfections. The destruction of these follicles may be accomplished in one of four ways: (1) By the use of chemicals, (2) with the urethroscopic knife, (3) by electrolysis, and (4) by the high frequency current.

There are other methods also, such as injecting chemicals with a fine syringe into the follicle openings, curettings, etc., but the four methods just enumerated are the ones most often employed, and sufficient for all cases.

Every one of the first three methods should certainly be mastered, as different methods must be employed for different conditions as will presently be described. The high-frequency method, lately advocated by Swinburne,[30] seems to be a very simple and efficacious method, but it requires the use of a high-frequency machine, an expensive luxury not enjoyed by everyone. It is certainly not worth while for one who does not specialize in genito-urinary work, and who is therefore not apt to treat bladder tumors, to get the machine simply for the purpose of destroying urethral follicles. As a matter of fact, every kind of follicle can be successfully treated by one or other of the first three methods.

1. *Technique of Destroying Follicles by Chemical Means.*—For this purpose silver nitrate is the best chemical. A minute piece of the crystal is fused upon the end of a very slender metal probe, care being taken that the end is not too thick to enter the mouth of the duct. After the urethroscope is *in situ*, we mop the urethra dry with a cotton applicator, and expose the follicle opening to be treated. Should it at any time become necessary to do any more mopping, it is best first to remove the lamp before the applicator is employed. This is done for the following reason: It is, of course, possible and more convenient to do the mopping with the lamp

in situ, but, unless the cotton is wrapped around the applicator with unusual tightness, it often happens that some small filaments of cotton come off and stick to the lamp. This ordinarily does no harm unless it interferes with vision, if any other method (knife or cautery) is employed for the destruction of the follicle. But if we use a chemical these filaments of cotton will take up some of the chemical while the probe is inserted, and parts of the urethra which we do not intend to treat may get the effect of the cauterization.

Having mopped the urethra dry, and having the follicle opening directly in view, we insert the probe carrying the caustic directly into the follicle opening as far as possible. It takes some experience to do this; in fact, more experience than when handling the knife or cautery. With the two latter methods, no harm is done by allowing the tip of the knife or cautery point to rest gently on some portion of the urethral mucous membrane, while we are groping our way to the follicle mouth. This is especially true when employing the galvanic needle or high-frequency method as we do not turn on the electric current until we are definitely within the duct. With the silver probe, however, any portion of the mucous membrane that it touches is immediately cauterized, a most undesirable result. It may perhaps be well for the beginner to manipulate the urethroscopic tube in such a manner that the follicle opening is near the edge of the tube, but away from the lamp. He may then run the probe along the edge of the tube, and so hit the opening. With experience, however, we can get the probe directly into the opening without touching any other portion of the urethral mucous membrane.

We try to get the probe to the very bottom of the follicle so as to destroy it as completely as possible. After the cauterization has been accomplished, we remove the probe as carefully as possible so as not to touch any other portion of the urethra. The beginner may follow the same procedure in removing it as in introducing it, namely, to keep to the edge of the tube. We immediately mop the urethra dry, so as to minimize the caustic action on the rest of the urethra.

We now slowly move the urethroscopic tube a little forward, looking in all the time in search for more follicles or other pathological conditions. Should we find two or more infected follicles very close together, it is not good policy to cauterize them all, as the resulting local reaction may be too severe. We simply treat one, and note the others on the history chart or diagram. Follicles, at some distance from each other may, however, be treated at the same sitting.

2. *The Destruction of Follicles with the Urethroscopic Knife.* (Fig. 3, B.) Having located our follicle as before, and decided to slit it open with the knife, we first make a careful inspection of it, and bring it clearly into view. We should make up our minds beforehand just how much and how far we intend to cut, and then go about it boldly and deliberately. The reason for this is, that as soon as the cut is made the portion of the urethra in view is so rapidly filled with blood, that our vision is obscured. Unless, therefore, the entire procedure is done rapidly we will not be able to finish our undertaking. There is no use of experimenting with the knife, by slitting up a portion of the duct and seeing how we get along. Unless we have our plan beforehand, we should not undertake it. In some cases it may be well to put the mucous membrane on the stretch in a drumlike fashion. The inexperienced is likely to be too timid with the use of the knife, but with ordinary care there is absolutely no danger in its use, and no danger in cutting too deeply.

3. *The Destruction of Follicles by Electrolysis.*—In the use of electrolysis, it is necessary to employ two different sources of electricity—one for lighting the urethroscopic lamp and the other for furnishing the galvanic current for the needle. If we employ the same source for both, the patient may get a very severe shock.

I generally employ a small dry-cell battery for lighting my urethroscopic lamp, and the regular Edison street current, with a rheostat, for the electrolysis needle. We put the cords upon the rheostat and connect the cord going to the positive pole with a flat abdominal plate or sponge which has been moistened with either salt water or vinegar water. If a plate is used, this is covered with a towel, wet as above, and the whole is applied to the patient's abdomen. The cord from the negative pole of the rheostat goes to the handle carrying the electrolysis needle. If we do not know which pole of the rheostat is negative and which positive, we determine this in the following manner: We insert the tips of the cords into a glass of salt water and turn on the electric current to its full extent. We shall soon notice very many bubbles collect at the end of one of the cords; this is the one connected with the negative pole. There may be a few bubbles also at the other pole, but the negative pole cord is the one at which they collect in large numbers.

Having located our follicle opening and mopped the urethra dry at that point, we insert the needle carefully into the opening, as far down as possible. We try as much as possible to get the needle directly into the small opening, so as not to touch any other portion of the urethra, which may cause bleeding and necessitate more mopping. We must also be careful not to touch the lamp carrier, as this may extinguish the light for the time being.

We start by having the rheostate at zero. Having our needle in the follicle opening, we connect the cord with the needle holder and gradually regulate the current with the rheostat, increasing the strength of the current till it is as much as the patient will stand, and until we see white bubbles come from the follicle mouth. We leave the needle in the follicle, with current turned on, for a few minutes, until we see that the follicle is entirely destroyed. If there should occur frequent touchings of the electrolysis needle with the light carrier it may be advisable to turn off the light while the electrolysis current is on, and then shut off the current from the needle while we look in to see how things are progressing. The experienced urethroscopist will, howver, have no difficulty in avoiding contact of needle and lamp.

In Wossidlo's clinic in Berlin it was the custom to use a milliamperemeter to regulate the amount of electrolysis; the current was increased until the milliamperemeter showed that there was passing only two or three milliamperes, and this was kept

up for two or three minutes. Experience has shown me, however, that this is neither necessary nor wise. Our object is to destroy the follicle, and we employ as much electrolysis and for as long a time as necessary to accomplish this result. We cannot give too much, as the patient will object.

We may by this method destroy as many follicles as we choose, or as much as the patient will stand at one sitting. The local reaction is very slight compared to the other methods.

4. *Destruction of Follicles with the High-Frequency Current.*—Swinburne[30] employs the Buerger instrument, and describes his method as follows: "During the examination, and during the treatment I always have an irrigator attached to the instrument, so that there is a constant stream of cold, sterile water running; and in turning on the electric current I simply leave it on for a second or so. If the water is not running, the sensation of burning is a little greater than when it is running. Patients very quickly get used to it, and do not mind it, though some make a good deal of fuss. I always begin at the deepest follicle that I can find and work my way forward. In some cases there are only two follicles, and in some, as I have reported, there have been as many as eight. At each follicle I turn on the electric current two or three times, doing it for one or two seconds each time, according to the way the patient acts. I have made examinations and treatment once a week; in the acute cases the patient uses his injection of silver once or twice daily at home during the interval. I do not recall having made more than three applications of the fulguration in any one case—*i.e.* in the acute cases. In some chronic cases I have made, I think, even four, perhaps more. This method has proved quite satisfactory in my hands."

It has been suggested, more upon theoretical grounds than anything else, that inasmuch as the follicle ducts do not run a straight course it is impossible to destroy them completely; that all we do is to close up the mouth of the follicle duct, thereby really doing more harm than good. It is true that if we were to make a microscopic section of the urethra after treating a follicle by any of the above methods, we would, in all probability, find that in a certain number of cases we have not destroyed the entire follicle. But for all *practical* purposes, if we discriminate as will be presently described, which follicles are to be treated by which particular method, the above objections will be seen not to hold.

Of course, if we have a very inflamed follicle, filled with pus and harboring gonococci, and if we close up the opening which drains this follicle, leaving the virulent infection within, we actually do harm. In such a case the germs continue to increase, the inflammation increases, as well as the pus within the follicle, and if the duct has been securely closed by our treatment an abscess will form, to break out externally, or anywhere at the point of least resistance, often in the most undesirable of places. But if clinically there is no inflammation within the follicle, even if some few gonococci should still lie dormant therein, the firm closure of the duct by electrolysis (not silver nitrate) will soon cause such gonococci to be shut off from the moisture of the urethra and all other nutrition, and they will eventually disappear. Whether this is the correct explanation or not, one thing is certain: that clinically, and later bacteriologically, such a follicle is destroyed, and no gonococci are harbored therein.

We will now take up for consideration the very important question as to which follicles and ducts are to be treated by chemical means, by knife, or by electrolysis. Only general rules can be laid down as there are endless varieties in the appearance of the follicle openings corresponding to the different grades of inflammation or infection present. As a general rule, I do not think it desirable to treat by chemical means those follicles which show much inflammation about their duct openings, or where much pus is seen oozing from the mouth of the duct. The chemical action of the silver nitrate will but increase the inflammation of the surrounding tissue, thus reducing its resistance, and making a more favorable soil for the multiplications of the germs. As a matter of fact, follicles that show much discharge had better be left alone, as the drainage is evidently good, and ought not to be interfered with. If the discharge has stopped, but the halo of redness is still seen, showing that there is some slight inflammation still present, we may, by the application of silver nitrate cause the inflammation to disappear. Follicles with very large openings are also better treated with chemical means than by knife or cautery. Follicles in which the openings are very minute, with pus exuding, and no gonococci found either on smear or culture, may be destroyed by electrolysis on the theory that, should there still be a few gonococci lying dormant in the interior of the follicle, the firm closure of the duct will cut off their nutrition from the urethral moisture, and cause them to be either encapsulated or otherwise killed from lack of nutrition. Follicles which are seen to be filled up with pent-up secretion, but in which the urethral opening of the duct is very small and the drainage therefore not as good as it should be, are best slit up with the knife. Our object here is not to destroy the follicle but to provide better drainage. With the knife we may also remove hard concretions which we may sometimes feel in the follicle. The high-frequency current may be employed wherever the electrolytic needle is employed. It seems to be a more convenient method of destroying a follicle, as well as a more certain method.

Urethroscopic Treatment of Other Pathological Conditions Found in the Anterior Urethra.—Warts in the urethra can easily be seen and treated through the urethroscope. They may be removed by either the high frequency current or the intra-urethral snare, by any sort of biting forceps which can be introduced through the urethoscopic tube, by slow cauterization with chemicals, or by electrolysis with the needle attached to the negative pole, just as has been described in the destruction of the infected follicles by this method. In most cases, however, the best method of removal is simply to scrape them away with the edge of the urethroscopic tube. This may not make a very pretty operation, but it is the most practical method in the vast majority of cases. As a matter of fact, many of the warts are scraped off by the introduction of the urethroscope.

The treatment of cysts is simply to tear them apart, with a needle such as is used for electrolysis or with the urethroscopic knife. There is very little bleeding following such destruction.

Urethral polypi may be removed either with the intraurethral snare, or by means of a special intraurethral scissors or biting forceps. The base, after removal, may be touched with silver nitrate.

Soft infiltrations may be treated through the urethroscope by swabbing the parts either with pure tincture of iodine or 2 per cent. silver nitrate solution. This swabbing is repeated every five to eight days, according to the reaction produced. As soon as all signs of local inflammation have disappeared, dilatation treatment, at first by sounds and later with the Kollmann dilator if necessary, should be instituted. The detail of this latter treatment is beyond the province of a paper devoted primarily to urethroscopy, but it should be instituted at the earliest possible moment. It is to the great credit of urethroscopy that such treatment, dependent upon early urethroscopic diagnosis, can be instituted at a time when no symptom of beginning stricture is evident, and that such early treatment will prevent a stricture with all its inconveniences and deleterious consequences. The treatment will cause an absorption of the small round cell infiltration, and will bring back the urethra to a perfectly normal condition.

The treatment of hard infiltration I believe to be beyond the province of the urethroscope. It is in fact already a stricture and should be treated as such. Asch[2] suggests that at the commencement we may try the same treatment by swabbing as was advised for soft infiltration. Of course there are borderline cases, in which one may be in doubt whether the condition has advanced beyond the soft stage into the hard one, and in such cases the swabbing method may at times bring about a cure; but I doubt whether in true hard infiltration such result can be obtained. There is no harm in trying for a little while, but dilatation treatment must not be too long postponed. Asch also suggests the use of the intraurethral curette for hard infiltrations. I have never tried this method, for theoretically, from a study of the pathology of the condition, I cannot see how it can possibly be of benefit.

Erosions of the mucus membrance are to be treated by swabbing them with a 10 per cent. solution of silver nitrate. In making such applications one should be be careful to have only a minute amount of cotton on the applicator, and not to have the solution dripping from the applicator so as to flow all over the rest of the urethra. The application is to be followed immediately by dry swabbing.

The treatment of membranous urethritis (above described) must be persistent and prolonged, and requires much patience on the part of both physician and patient. It is necessary to remove as much of the membrane as possible, and touch up the underlying mucous membrane with one or two per cent. silver nitrate. The removal of the patches causes no bleeding. Asch[2] has suggested curettage of the urethra for the relief of this condition. Whatever method may be employed, it must be persisted in until all tendency to membranous formation has disappeared.

INTUBATION IN LARYNGEAL DIPHTHERIA;

WITH NOTES ON SIXTY-FOUR CASES

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

Before discussing the subject in question I deem if opportune again to recall the great services rendered by the master of intubation, the late Dr. Joseph O'Dwyer of this city, who after numerous failures and discouragements finally succeeded in presenting to the world a priceless gift in the form of an intubation set, which has saved multitudes of children from gradual, agonizing death. Before this marvelous invention was fully accepted by the medical profession he had been frequently humiliated by incompetent and possibly envious critics, rather than honored, remunerated, and decorated, by the State or country, or perpetuated in bronze or granite, as he surely would have, had he been as successfully engaged in the acts of destruction, in the art of warfare.

During the past five years I have had the privilege of intubating sixty-four children suffering from laryngeal diphtheria, with but one fatal issue. I feel certain that this favorable result was due to the facts, firstly, that the physicians in attendance had promptly administered ample doses of antitoxin to neutralize the diphtheritic toxin; and secondly, that they used the good judgment to invite me to perform the operation while their patients were still in fair vitality, and not gasping for the last breath of air, as is often the case with those sent to hospitals for contagious diseases. It may be noted that all of these children remained in their own homes, often in most undesirable surroundings, and without skillful nursing. Four of them lived out of town, requiring two or three hours' journey to reach. To emphasize the absolute feasibility and perfect safety with which intubation can be performed even under the most trying conditions, let me briefly relate the following case:

L. P., 4 years old, the son of Slavish parents in the poorest district of Perth Amboy, N. J., had been ill for three days before consulting Dr. S. Finding involvement of the nasopharynx and larynx, he immediately administered 10,000 units of antitoxin and prescribed other remedies ordinarily in use. During the night the child got very much worse and the laryngeal stenosis had assumed alarming intensity by the time we arrived there. Owing to considerable tumefaction and unusual depth of the larynx, intubation was somewhat difficult, but the boy obtained prompt relief with introduction of the tube. After giving another 10,000 units of antitoxin and ordering absolute rest, we left the child, practically without any specific directions, under the care of the mother, who was entirely helpless and unable to understand our language. Five days later we returned for extubation, and, to our great amazement, were met at the door by the little patient, tube still in the throat, but apparently perfectly happy. Extubation was comparatively easy, and the boy required no aftertreatment whatever.

This case, among several similar ones, has fully convinced me that intubation can be performed without hesitancy even in the humblest of homes without any preparations or skillful aftertreatment. This optimism is not shared by a goodly number of clinicians, one group of whom, discarding intubation entirely, as a dangerous operation, and preferring tracheotomy, with the certain dangers and disadvantages of hemorrhage, secondary infection, tracheal fistula, stricture of the larynx, delayed convalescence from a slowly healing wound, and a disfiguring cicatrix; and another group of physicians, who, though recommending intubation in preference to tracheotomy, are nevertheless quite timid in accepting it as the operation of choice in all cases of laryngeal stenosis. They lay particular stress upon the risk of the tube causing ulceration of the larynx, or the danger of return or increase of the dyspnea, either by pushing false membrane before the tube or blocking it while in the larynx, and also of expulsion of the tube by coughing or otherwise. Now I do not at all hesitate to say that those who claim intubation to be a dangerous operation have never had the opportunity or inclination to learn the operation under the guidance of a competent instructor, nor have they given it a fair trial. In the many years of experience with intubation I have never met with the aforementioned difficulties, and I believe that this is due, firstly, to the fact that with the early administration of antitoxin the virulent types of diphtheria of olden times are of very exceptional occurrence nowadays; and secondly, to the care and scrutiny in the selection of the cases and strict attention to the principles and technique as handed down to us by the late Dr. O'Dwyer.

To begin with, we must be absolutely positive that the cases in question actually require intubation. On several occasions I have been invited to intubate children who, instead of suffering from laryngeal stenosis, were in reality in the last stages of pulmonary edema, complicating pulmonary or cardiac disease. Recently I was called to intubate a fifteen-months'-old infant supposedly dying from diphtheritic laryngeal stenosis. The baby did have tonsillar diphtheria, but I could find no trace of laryngeal involvement, the noisy breathing having been due to intense dyspnea accompanying myocardial disease. I declined to intubate, and advised heart stimulants. The parents of the child, however, could not be reconciled to this view, seeing that the "baby was choking," hence insisted upon getting a throat specialist to intubate. This was done two hours later, with the result that the baby died during the operation.

The next point of importance before proceeding with intubation is to be certain that the instruments are in perfect working order. Particular attention should be paid to the construction and condition of the tube, more particularly that it be free from rough or sharp metal edges, for otherwise, when during the act of swallowing the epiglottis and upper end of the tube are pushed posteriorly by the backward pressure of the base of the tongue, and the lower end of the tube is pressed forward, the gliding movement of the rough tube is very apt to injure the anterior wall of the trachea and thus to produce the ulceration of the larynx previously spoken of. We must also note that the obturator fits snugly and that the tube selected corresponds to the size of the child's larynx.

After having ascertained these details to our entire satisfaction we may then proceed with the

operation. The patient is placed upon a strong table, and, from shoulders down, wrapped tightly in a small sheet or blanket, fastened by several strong safety pins. An assistant standing at the head of the table inserts a mouth gag in the left angle of the child's mouth, well back between the teeth, and opens the gag as wide as possible without using undue force. The same assistant steadies the patient's head and holds the gag in place. The operator, standing to the right and in front of the patient, holds the introducer lightly between thumb and fingers of the right hand, with the thumb resting just behind the button that serves to detach the tube, and the index finger in front of the trigger underneath. The index finger of the left hand is now gently passed into the pharynx, down to the beginning of the esophagus, and by bringing the finger forward in the median line and raising and fixing the epiglottis, the tube (threaded with silk to prevent it from slipping into the stomach in case it is wrongly put into the esophagus) is gently introduced along the left index finger into the larynx. The left index finger is then quickly put on the shoulder of the tube, and the introducer, with obturator, is withdrawn after pushing its upper button forward. After the tube has been securely pushed home the mouth gag is removed, but the silk thread is left in the tube for about ten minutes, until it has been ascertained that the dyspnea is relieved and no loose membrane is crowded down in the lower portion of the trachea. In removing the thread, the finger is reinserted to hold the tube in place. As a rule, introduction of the tube is followed by an active spell of coughing, which generally expels mucus and bits of membrane that may have been lodged in the upper respiratory tract. Should we fail, however, to relieve the dyspnea, it is advisable immediately to remove the tube by pulling the thread, to induce emesis and expulsive coughing by tickling the child's palate and throat with spoon or finger, and then to reintroduce the tube, or, if the case be very urgent, to use a smaller tube temporarily. There is never any danger in repeated intubation, or even failure to intubate, provided the operation is performed very gently—more particularly so as not to force a false passage—and the index finger is not allowed to rest upon the upper portion of the larynx too long, so as to obstruct the air passage.

The aftertreatment consists in keeping the patient quiet, preferably in a recumbent posture, application of an ice collar around the neck, and administration of antitoxin (if needed) and small doses of bromide, strychnine, and stropanthus. Feeding may be resumed a few hours after intubation: in babies, breast or cow's milk in small quantities, by means of a spoon; in older children, semisolid substances, such as custards, wine jelly, junket, soft-boiled egg, ice cream, and the like. Small pieces of ice may be given instead of water. It is often of advantage to feed the child with the head lower than the body.

With the absolute subsidence of the dyspnea and temperature, which usually occurs in from three to seven days, we may proceed with extubation. It is always advisable to have another tube ready for immediate reintubation in case removal of the tube is followed by return of intense dyspnea. The patient is prepared in the same manner as for intubation. The extractor is guided along beside the left index finger and very gently inserted into the aperture of the tube. The engaging terminal blades of the extractor are opened by lightly pressing upon the upper arm of the extractor, which is then promptly withdrawn from the throat. This maneuver is not always very easy, but even repeated failure will do no harm, provided no force be employed. Occasionally one succeeds in removing the tube by "stripping" the larynx from below upward with one hand, at the same time grasping the head of the tube between the index and middle fingers of the other hand.

As a rule, these procedures end the operation. On rare occasions, however, there is an immediate return of the asphyxia. In this event, unless the dyspnea assumes extraordinary gravity, we may administer an emetic (apomorphine) or minute dose of morphine and atropine hypodermically, and spray throat with a one or two per cent. solution of cocaine until the spasmodic stenosis has been relieved.

A few months ago I had the opportunity of convincing myself of the efficacy of this preventive measure in a very severe case of post-extubation asphyxia, although it required about twenty minutes to accomplish it. I recall but one instance where I was obliged to reintubate three times, and the case failed to show diphtheria bacilli after repeated laboratory examinations. In these cases, which are generally spoken of as "retained intubation tubes," we usually remedy the trouble by gradually introducing larger tubes with each reintubation and by local attention to the nose and throat.

To counterpoise the admonition frequently given, "never to intubate patients who are extremely asphyxiated" (*e.g.* E. W. Goodall, *Intern. Med. Ann.*, 1907), I may be permitted to relate the following instructive experience:

J. D., 5½ years old, had been coughing croupy for three or four days, and, as the parents were poor, was treated by them with the usual home remedies. In the middle of the night his condition became so alarming that they hurried for a neighboring physician. Finding that the boy was suffocating from diphtheritic laryngeal stenosis, he promptly summoned me to perform intubation. As I entered the dingy and foul smelling room I was greeted with "It is too late, Doctor." Indeed, the boy was actually in the last stage of asphyxia, his face bluish black, his eyes protruding and suffused, his breathing suspended, and his entire body perfectly limp—apparently dead but for a barely audible fluttering of his heart. I remarked to my colleague that since we were not going to be paid for our visit anyhow, we might as well gain something from the additional practice in intubation. Thereupon I quickly inserted a tube in the boy's larynx, carried him to the front of an open window and injected one-twentieth of a grain of strychnine hypodermically, while Dr. F. proceeded with artificial respiration. There was shortly a marked change for the better and the child improved so rapidly that, after administering 10,000 units of antitoxin, we were able to leave him under the care of his mother within about an hour after our arrival. I extubated six days later and the boy recovered fully without any further attention.

I need hardly add that after this and similar experiences we could not help but become enthusiastic advocates of intubation in preference to tracheotomy.

127 West Eighty-seventh Street.

THE REORGANIZATION OF THE NEW YORK CITY CHILDREN'S HOSPITAL AND SCHOOL.

By WILLIAM BURGESS CORNELL, M.D.,

NEW YORK.

MEDICAL DIRECTOR OF THE N. Y. CITY CHILDREN'S HOSPITAL AND SCHOOL.

THE reorganization of the New York City Children's Hospital and School, which was begun in 1915, marks an important epoch in the care and treatment of the feebleminded.

The history of the Randall's Island institution dates back to the mid 30's or shortly after the property was acquired by the city of New York. The first institution on the island was a branch of the city almshouse. In 1848 the first extensive group of buildings was finished and occupied, and the report for that year states that it is the "most complete, convenient, and elegant establishment for the rearing of young orphans of the city's care known in the world."

From the first it is evident that an indiscriminate variety of cases of all ages was admitted; this was even further amplified after the institution came under the supervision of the Department of Charities and Correction in 1860 by the addition of prisoners from the Penitentiary and Workhouse on Blackwell's Island. These prisoners, who were of the usual workhouse type, were required to perform much of the labor in and about the institution, and they remained in this capacity on the island until the division of Charities and Corrections into separate departments. The almshouse nature of the institution is indicated as late as 1914 by the perusal of the New York Charities Directory (p. 390) for that year. The following is quoted therefrom: "The Randall's Island institutions also receive defective children who are too young to be sent to institutions for special training, or who for other reasons will not be received by other institutions. In fact, any destitute, sick, or defective child, whose particular circumstances and condition do not fall within the requirements of any other institution is likely to find his way to Randall's Island." In 1914 efforts to bring about a more uniform classification were inaugurated and by 1915 almost all the inmates of "normal" mentality, including cripples, were transferred elsewhere.

It is interesting to trace the origin of the name of the institution—The Children's Hospital and School—which is singularly appropriate and avoids the use of either of the objectionable words—"feebleminded" and "asylum." The progressive increase in size and the wide diversity of cases resulted in the development of separate institutions. In 1875, there were separate reports from the Randall's Island Hospital, the Infants' Hospital, the Idiot Asylum, and the School for Feebleminded. A consolidation of all except the Infants' Hospital was effected in 1892. Ten years later all the institutions were united under one superintendent and named the Randall's Island Hospitals, Schools, and Asylum. This title was subsequently changed to the Children's Hospitals and Schools, and modified in 1916 to the Children's Hospital and School.

Practically all the buildings, which were the "most complete in the world" seventy years ago, are still standing and in use, although badly worn and unfit for occupancy. To the original nucleus, scattered over a long period of years a few additions have been made, notably the nurses' home, power house and laundry, and gymnasium; but with two exceptions, the reception hospital and Jacobi ("G"), each of 80 beds, no new accommodations for patients have been provided since the late 60's or early 70's. Furthermore, the physical plant was allowed to deteriorate as fast as natural processes would permit. Realizing the necessity of rehousing the patients, Commissioner Kingsbury obtained an appropriation of $600,000 in 1915 and $1,000,000 in 1916, and at this writing there are twelve new buildings under construction, ten of them wards to accommodate 1,400 patients. These structures are being built in the most substantial manner and will be the last word in the housing of the feebleminded. The plans were drawn and supervised under the direction of Dr. Walter E. Fernald of the Massachusetts School for Feebleminded at Waverley. It is hoped the new buildings will be occupied during 1918, and at the same time that many of the outworn structures will be razed. Another appropriation of at least $1,500,000 will be required to complete the modern housing of the entire institution to care for 2,000 patients.

The medical work and administration were formerly carried on by a medical board, serving gratuitously, composed of practising physicians residing in the city. They were assisted by a staff of resident internes varying from one to four in number and receiving a small compensation (usually $10 per month).

The reorganization brought about in 1916 placed the supervision of all departments of the institution in the hands of a medical director and a staff of nine physicians, including a pathologist. The old medical board was reorganized as well and renamed the medical council, the executive function of the former being transferred into advisory and consulting. In addition to the latter, Commissioner Kingsbury appointed an advisory board composed of prominent citizens, both lay and medical, interested in various sides of the problem.

The clinic for atypical children, formerly independent of the institution, but a part of the central office organization of the Department of Public Charities and located successively at the Post-Graduate Hospital, Bellevue Hospital, and 57 East 125th Street, was moved to Randall's Island in August, 1917, and became an integral part of the institution. the name "Mental Clinic" having been previously substituted for its former title.

The staff of the clinic, consisting of two physicians, two nurses, two stenographers, and one psychologist, became united with that of the institution and works interchangeably with the latter. This combination gave a total of twelve physicians and two psychologists to the institution, probably the largest staff of any hospital of similar nature in this or any other country, but really too small to take care of the 3,000 cases which pass annually through the clinic, or the 1,000 or more new admissions each year to the institution which has a daily average census of over 2,000.

The clinic on the island is open daily from 9 until 11, except Monday and Tuesday, when it is held at the Cumberland Street Hospital, Brooklyn, to accommodate the Brooklyn and Queens patients.

Patients are referred from public and private agencies, by the courts, and by physicians, or they may come voluntarily or through their families or friends. Other mental clinics and the ungraded classes of the Department of Education also refer cases for admission. In each instance when they have been previously examined or have been known to charitable organizations, an abstract or transcript of record is asked for to save wasteful repetition of work. All applicants for admission to the Craig Colony for Epileptics, to Letchworth Village, Newark, to the Rome Custodial Asylum, or to the Syracuse State Institution for Feebleminded pass through this clinic, and many of the cases come to Randall's Island pending admission in one of these up-State institutions.

Only recently has a definite policy been formulated as to the scope and function of the institution. Now only the feebleminded, or those suspected of being feebleminded, and the epileptic who reside in Greater New York are admitted. Borderline and problem cases are also received for study and disposition. More and more is the institution developing into a clearing house where intensive study, treatment, and training may be carried out according to the most approved and latest methods, and with this is disappearing the custodial asylum feature which has represented so much of the work of the institution in the past. To achieve this end, the accumulation of the low grade and helpless patients of idiot class must be relieved by adequate State care of the feebleminded. Basing our figures on the averaged estimates of a number of reports (Fernald, Johnstone, Goddard, and Kuhlmann) and surveys (Porter County, Ind., Nassau County, N. Y., and New Castle County, Del.) the State of New York has suitable provision for only one-tenth of the feebleminded in the State. In view of this fact, it is evident that the Randall's Island Institution cannot either meet its share of this public need or accelerate sufficiently the movement of population within its walls, until the State provides proper receptacles for the cases which must go to State institutions, and only then will the institution assume what I think is its real place in the commonwealth.

Admission to the institution is obtained usually after the patient has been seen at the mental clinic and a report received from the Bureau of Social Investigation as to the acceptability of the case as a public charge. Relatives able to reimburse the city wholly or in part are expected to do so. The large majority of the patients are referred to the institution by other agencies and are held without commitment. About ten to fifteen per cent. (under the age of 16) are committed by the Children's Court, and a very small percentage are committed directly as feebleminded under Chapter 361 of the laws of 1914.

The work of the institution consists of two main divisions, medical and educational. On admission the following are routine procedures: Culture for *B. diphtheriae*, Wassermann test, Schick test, typhoid vaccination, vaginal smear, urine examination, and physical and mental examinations.

After completion of the record, cases are presented at the daily morning staff conferences for diagnosis. Presentations are likewise made for consideration of discharge, placement in service, etc. These conferences are attended by physicians, psychologists, the supervisor of training, and field workers. Stenographic notes of the proceedings are taken and recorded in patient's record.

The institution is well equipped in personnel to handle every phase of the main subject. The medical council is composed of well-known specialists, who are on call for any assistance desired in the following branches: Internal medicine, surgery, orthopedics, dermatology, neurology, psychiatry, roentgenology, ophthalmology, laryngology, oral surgery, and endocrinology. It is planned to increase the physical equipment to the high plane already reached in the personnel.

The educational department embraces all branches of training, including organized play and recreation. At present there is a teaching personnel numbering thirty-six, and it is planned to increase this to forty in 1918. The scholastic work is now congregated in one building, and the industrial and manual work is likewise segregated. It is desired to give a full day's program to every child who is capable of training, for which the findings of the psychological examination form the basis. No time is wasted in trying to force training upon a patient who is unable to profit thereby. The following branches are taught: Scholastic, Seguin, singing, orchestra, band, gymnasium, sewing, dressmaking, power-machine operating, fancy needlework, weaving, applied art, basketmaking, raffia work, carpentry, cobbling, rug and mat making, household service, including cooking, and table waiting, and gardening. Printing, cement molding, brush and broom making and book binding will be added shortly. For young children and the low grades, a greater application of sense training and kindergarten work has been established. For the blind and near-blind, the New York Association for the Blind has generously supplied two teachers, and for a year past these doubly handicapped patients have had both training and recreation.

Disorders and defects of speech are common in the mentally defective. Organized efforts to study and treat these conditions have been made during the past year under the supervision of Mrs. E. W. Scripture.

It is felt that fully 100 per cent. more patients are receiving some form of training than formerly.

The single idea of the institution is the study, treatment, and training of the *individual* whether he be feebleminded, epileptic, or exhibit some phase of conduct disorder, and it is hoped that this may be carried out in spite of large numbers that must be dealt with, by systematic and cooperative effort. In this way it is confidently felt that valuable results will be obtained and the wonderful opportunities for human service will not pass neglected.

Poisoning with Chlorine Gas.—Kramer reports a case of industrial poisoning with chlorine gas fumes. The symptoms were much like those in military cases, but the case ended fatally after an interval of twenty days, a course not often seen in the latter. The blood contained many myelocytes and normoblasts with an unusual progressive tendency to thrombosis, to which the fatal result may be attributed. These blood finds are said to be unique.—*Vierteljahresschrift für gerichtliche Medizin.*

THE SIGNIFICANCE OF NEGATIVE SPUTUM EXAMINATIONS IN PULMONARY TUBERCULOSIS.

By MORRIS H. KAHN, M.D.,

NEW YORK.

A SURVEY of the records of patients under observation for suspected pulmonary tuberculosis reveals many cases with equivocal lung signs. Cases of asthma, emphysema, and chronic bronchitis, of atherosclerosis or myocardial disease with pulmonary congestion are frequently under supervision for long periods in the tuberculosis clinics of the Department of Health.

It is admitted that early diagnosis of tuberculosis is most important from a therapeutic and prognostic standpoint, and it often happens that in these cases the tubercle bacilli may be present in very small numbers only. Sputum examinations are made at irregular intervals, and when these occasional examinations are returned negative, the diagnosis remains undetermined. Sanatorium treatment is often undertaken and a negative diagnosis may be reached after a sojourn of several months in the country.

The various methods of diagnosis outlined in a previous paper are all of considerable importance, and at times of invaluable assistance in the study of any particular case. The Arneth blood count, the cytological examination of the sputum, *x*-ray of the lungs, and complement fixation by tubercle bacillary antigen are methods not to be neglected, where no decision is otherwise reached. Absolute certainty in the diagnosis, of course, can come only with the direct demonstration of the tubercle bacilli in the sputum.

The present study was undertaken: (1) To ascertain the significance of persistently negative sputum examinations in pulmonary cases. (2) To advocate the collection and examination of twenty-four hour specimens of sputum from all pulmonary cases in preference to a fresh sample of the morning sputum alone, as is usually advised. I have indications that this special point is of value where occasional sputum examinations have repeatedly been found negative. My data on this point are as yet insufficient to record here in detail (See Kahn, M. H.: *Journ. Lab. and Clin. Med.*, 1916, I, No. 8). Naturally the entire twenty-four hour quantity should be subjected to homogenization or should be centrifuged to collect the bacilli for microscopic examination. It is also desirable to examine the daily specimens for a period of about two weeks.

In Table I is an analysis of 82 cases that died as a result of pulmonary tuberculosis and came to autopsy at the Metropolitan Hospital during 1914. Only those cases are included in which postmortem diagnosis corroborated the clinical findings and in which sputum examinations were made either at the hospital or in the municipal Diagnostic Laboratories.

The reason that only the records of 1914 were deemed suitable for the study was that after that year, no cases were admitted to the hospital without a previously reported positive sputum examination. As is seen, all the cases showed positive pathological evidence of pulmonary tuberculosis after death.

TABLE I.

Case No.	Path. No.	Post Mortem Pathological Findings.	Sputum	
			Neg. No. Exam.	Pos. No. Exam.
1	2000	Chronic pulmonary tuberculosis with cavities. Acute miliary tuberculosis. Tuberculous pyelonephritis. Tuberculosis of prostate and bladder	3

82	2198	Chronic pulmonary tuberculosis, with cavitation....		1

Unfortunately the lungs were not kept for bacteriological or microscopical study. The records of the Department of Health and all other available records were searched for the results of sputum analyses of these cases.

A numerical tabulation was also made of the cases divided into two classes according to the extent to which the tuberculous processes in the lungs progressed, that is (1) miliary lesions, consolidation, and caseation, and (2) the presence of cavity formation. (See Table II.)

It may be of interest to mention the occurrence and localization of tubercle bacilli in pulmonary lesions.

The tuberculous process and the secondary foci go through stages of cell growth, necrosis, and connective tissue development. In the most chronic varieties of tuberculosis the development of fibrous tissue is the predominant feature, and this leads to a thickening of the interalveolar, peribronchial, interlobular, and subpleural connective tissue. Tubercle bacilli are found in and among the various cells, but not in the fibrous tissue itself.

A caseous or necrotic change is probably never altogether absent at some period in the development of any tuberculosis formation, and as a rule this is the prevailing feature. In caseous material tubercle bacilli are generally very scanty.

When softening goes on to excavation, suppuration may be excited by pyogenetic cocci and perhaps also by the tubercle bacillus, and in cavities the tubercle bacilli are found in immense numbers.

Though the number of cases is far too few from which to draw any conclusions, and the accuracy and absoluteness of the negative sputum reports are liable to question, it may be of interest to analyze the findings as far as they go.

TABLE II.

Autopsied Cases 1914	Cases with Negative Sputum. 1 Exam.	2 Exams.	3 Exams.	Cases with Positive Sputum. 1st. Exam.	2nd. Exam.	3rd. Exam.	4th. Exam.
Cases with miliary lesions consolidation and caseation	1	1	8	8	2	0	0
Per cent	5	5	40	40	10	....	
Cases with cavitation.....	1	2	14	33	6	....	6
Per cent	1	3	23	53	10	....	10
Total number cases	2	3	22	41	8	*	6
Per cent	2.4	3.6	26.8	50	9.7	*	7.3

*No cases with only three examinations.

A review of Table II shows the following facts:

1. Of the 82 cases autopsied, 20 are classed in the group with miliary lesions, consolidation, and caseation, and 62 are cases showing cavity formation.

2. Three consecutive sputum examinations were made and proved negative in 8 cases, or 40 per cent. of the first group, and in 20 cases, or 33 per cent. of the second group. It is thus evident that three successive sputum examinations made at irregular intervals may be negative in a good proportion of cases showing advanced pulmonary tuberculosis. With the formation of cavities the likelihood of three successive sputum examinations being negative is lessened.

3. Of the total number of 82 cases that died from pulmonary tuberculosis, 28 cases, that is one-third of all cases, showed sputum negative in 3 consecutive examinations.

4. Six cases which showed cavity formation postmortem had three successively negative sputum examinations within a few months before death. This would suggest that several negative sputum examinations should bear little or no weight in making a decision as to whether a case is tuberculous or not.

5. The sputum was positive in 10 cases, or 50 per cent., of the cases of the first group, and in 45 cases, or 73 per cent., of the cases of the second group.

6. Of these 55 cases with positive sputum 41, or half of all cases, were positive in the first examination made.

Perhaps the analysis given in this paper will stimulate a comparative study from the records of various other institutions where the sputum examinations were made more often, and where a larger amount of material may serve as the statistical basis for the conclusions derived.

Malaria Carriers.—Kaminer and Zondek have found malarial parasites in the blood of apparently healthy subjects. The latter were at least fever free, and aside from a little headache and lassitude did not complain.—*Deutsche medizinische Wochenschrift.*

Camphorated Mucilage in Fetid Wounds.—German surgeons have used this preparation extensively in gangrenous wounds with good results. Not only is the fetor abolished, but separation of the sloughs and healthy granulations are promoted.—*El Siglo Médico.*

AMAUROTIC FAMILY IDIOCY OR INFANTILE DEGENERATION WITH SYMMETRICAL BILATERAL BLINDNESS.

By EDWARD J. BERNSTEIN, M.D.,

DETROIT, MICH.

AMAUROTIC family idiocy is a disease so rare in most parts of the country, and of a nature to interest pediatrists and neurologists equally as much as ophthalmologists, that it seems an account of a case coming under my care would be of interest.

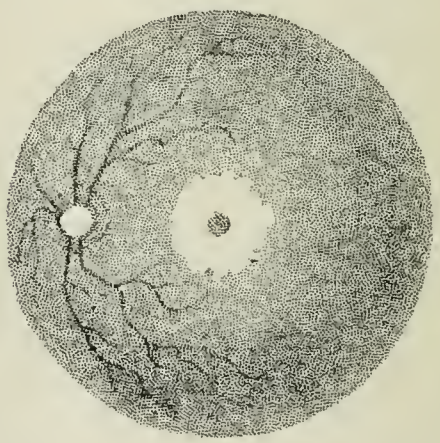
This is a disease which very strangely affects babies of Russian Jewish parentage almost exclusively. The children seem to be quite normal until about the fourth or fifth month, when the mothers begin to notice that the child fails to respond as it had done, the most noticeable factor being failure to follow the mother with its eyes, and a growing feebleness, usually beginning in the muscles of the neck and gradually extending to the whole musculature, ending in complete paralysis, marasmus, blindness, and death before the second year of life. The disease usually attacks two or more members of the same family, hence its name; as many as five in one family have been reported.

Though I have been connected with eye clinics in one capacity and another for nearly thirty years, this is the first case that I have ever seen, and in speaking to a number of the ophthalmologists here in Detroit, that about corresponds to their experience. Only one or two men had seen any. Notwithstanding this rarity, but because of it, we should all know about it and be prepared to recognize it. The etiology of the disease is absolutely unknown; it certainly is not syphilitic, traumatic, infectious, or tuberculous. It has been said, and this is held by most writers, that it is due to consanguinity of parentage; but some years ago I had occasion to look up the matter of consanguineous marriage as a cause of another malady, and I am convinced that it has nothing at all to do with it. Firstly, marriages among cousins is not at all uncommon among Jews generally, and idiocy or cerebral degeneracy is not one of the frailties of the Jewish people, whatever else may be said about them. Moreover, it is an unwritten law in the family of the Rothschilds that they marry cousins, and no one has seen any mental degeneracy in that family. In certain tribes of the interior of Africa, intermarriage is even more close, even brother and sister marrying, and they breed a very sturdy race of men. In certain groups of the Polynesian Islands, polyandry is practised to a large degree, one woman serving all the members of one family, and yet they also breed strong, healthy individuals. Consanguineous marriages are very common among all the nobility of Europe and aside from those diseases due to profligacy, there is no evidence of idiocy or lack of vigor. Neither profligacy nor lack of mentality are large factors among Jews. The fact that this disease is almost entirely found among the offspring of Russian Jews points to some particular factor in their make-up. The fact that many of the parents of these children acknowledge blood-relationship is not surprising, but to assign that as its cause, seems untenable. My own idea is that the degeneracy is due to the terrible economic conditions; the nerve-racking fear and the starvation and misery of their lives in Russia have much more to do with it, than anything else as yet brought forth. However that may be, the sad fact remains that nothing we can do has the slightest influence in diminishing the trouble or staying the death of the infant, which usually comes before it reaches its second year.

The picture of the eye backgrounds and of the general progressive paresis is unmistakable once it is seen. I am perfectly free to confess that when I first looked into the eye I could not definitely make the diagnosis, as it, in a measure may be taken for a new growth in the choroid—either tuberculous or leucosarcoma, a coloboma congenitalis, an embolus of the central retinal artery, or the maculocerebral degeneracy.

Maculocerebral degeneracy occurs usually about puberty and does not lead to complete blindness nor to paralysis or death, nor does it occur at all among Jews. An embolus of the central retinal artery is so rarely bilateral that only four or five cases have been recorded and they do not usually come at all in children.

Returning to the question of consanguinity of



Fundus of the left eye in a case of amaurotic family idiocy

parentage as a cause for diseased conditions, to refute that theory it is only necessary to call attention to the fact that breeders of live stock produce their best strains by this very process, selecting, of course, only healthy parents. It is evident that when both parents are below standard they will produce weaklings and that seems to be the case in this instance.

The pathology of the disease is pretty well worked out by many observers on this subject. It is a general ganglion-cell degeneration from the cerebral cortex throughout the whole nervous system. The picture we see in the eye—the large whitish area surrounding the central yellow spot, which shows out as round maroon-colored spot, is whitish and considerably elevated above the surrounding tissues and is due to the degeneration of the ganglion layer in the retina. At the macula region the ganglion cells are densest, gradually thinning out toward the periphery, so that while the ganglion cells throughout the retina are degenerated, they show most distinctly around the yellow spot, while directly in the center of the macula, there being no ganglion cells, that spot shows red.

The history of the case is as follows:

C. G., aged nine months, was referred to the eye department of the Grace Hospital from the pediatric department by Dr. A. Metzner, to ascertain whether the baby's apparent dullness was cerebral or due to the eyes. Up to its fifth month it had progressed normally, but gradually the mother noticed that the child did not follow her with its eyes as she moved about its bed. It developed an attack of whooping-cough about this time, from which it has recovered. The child is well-nourished and grasps fairly well and has not yet developed much weakness about the neck or thoracic muscles. Judging from the attack of whooping-cough, I thought central retinal artery embolus was the cause of its apparent blindness, but later and more thorough examination showed my error.

In the early stage at which I first saw the eyes (the condition was symmetrical in each eye), the whitish area seemed so distinctly elevated above the surrounding retina that I was not sure but that it indicated a growth between the choroid and the retina. The small retinal vessels pursued a tortuous direction as in new growth formation, but it merely means that in this case I caught the case while the cells were still swollen —later on they will atrophy and the retina will smooth out.

The parents are not related. They have three other living healthy children. A baby died three years ago, and so far as I can learn it was well until five months old, when it began to fail much as this one has, and died at the age of two years. It was seen by several medical men at the Children's Hospital, and a diagnosis of amaurotic family idiocy was made.

As far as I can learn these two cases are the first to have been recognized in Michigan.

IODIZED HYDRIDE ANTISEPSIS A HALF CENTURY AGO.

By ROSE F. OFRIAS, Ph.G.,

NEW YORK.

APOTHECARY TO THE KNICKERBOCKER HOSPITAL.

In 1842 iodine came into the U. S. P.; in 1858 Snow and Sir James Simpson were experimenting with an anesthetic called hydride of amyl, and about the time of our own Civil War the halogen and the lightest known liquid were mixed and the mixture was employed for antiseptic purposes. A notice of the solution may be found, upon page 554 of Dunglison's Medical Dictionary as late as the edition of 1873, wherein these words appear:

"Iodized Hydride. A solution of iodine in amyl hydride, grains xx to ʒi. When applied to the skin the hydride evaporates, leaving the iodine equally distributed on the surface."

The book also records the employment of that solution upon various septic processes, notes its value as a deodorizer, and explains that amyl hydride is a local anesthetic to be used in an atomizer or spray apparatus, together with its possibility as a means of administering iodine by inhalation.

Some years later when this amyl was derived from coal tar, its formula of C_5H_{12} led to the name of pentane, by which it is now generally known. If one puts a quantity of half strength tincture of iodine upon a cut or upon a wound he will at once recognize the roughness of that tincture, especially if he institutes a comparison under like conditions but using the milder iodized hydride with its *larger* iodine content. If anyone is so unfortunate as to have a boil he may yet be fortunate if he gain a clear, a definite, and a practical knowledge of the entirely different qualities of the alcoholic and the amylic, when their peculiar individual and counter-irritant capabilities are contrasted and studied through *personal* rather than *clinical* experience.

Modern ideas of normal healing are inclined to give much credit to the defensive powers pertaining to blood-serum and to antibodies. Those powers do play such leading parts in the matter that dilution or any other obstacle in the way of the exercise of their entire activity is something to be avoided when possible. On the other hand, animal wound-repair substances should be aided or concentrated but should never be weakened by extraneous foreign fluids. Under all the circumstances water might be graded as the worst possible diluent, alcohol perhaps is less so, but amyl hydride with its rapid evaporation is scarcely more than a brief or trivial interference with nature's methods. This hydride penetrates, evaporates, and discharges its burden of iodine exactly where it is required to build up a wall between germs and tissues. The latter are not attacked by it, but furnishing secretions the iodine is dissolved thereby and is carried in turn to a site of maximum efficiency. Meanwhile the harmless volatile amyl has gone into space, having served its purposes and departed.

Considering the present abnormal conditions of the market for alcohol and admitting the prejudices that have arisen against that drug, why not give this old solution a trial? The men of fifty years ago had liniments, tinctures, and all sorts of iodine-bearing preparations, yet they used this application with approval. It is stabile, does not change with light, nor does it precipitate. Its vial does require a good and a properly placed cork, since the contents are volatile. Its strength may be modified or mitigated for an individual patient, though it is more than doubtful if any alteration of the original formula will commend itself by trial.

The solution has been used in or upon severe septic wounds when the writer as an onlooker expected a jump and an outcry from the patient who was not incommoded in the least. On the contrary, the persons who submitted to its application upon laceration, boil, or ulcer described the after sensation as "good." How any iodine could feel "good" it is difficult to imagine, but that word was the one used by the patients themselves, who had had previous experience with the tincture. If internal use is desirable it is perfectly feasible to give it in capsule or in dilution.

The question that prompts the present paper is: Have we gone much beyond the men of a half century ago in the matter of iodine? The writer thinks that in clinic and operating room very possibly we have retrograded and therefore suggests the rehabilitation of an old method of skin and wound antisepsis. Sometimes much progress may be made when standing fast on ancient paths.

Medicolegal Notes.

Practising Without License—Use of Religion and Patent Medicines.—Under New York Public Health Law (Consol. Laws, c. 45) § 173, prohibiting the practice of medicine without a license, but excepting the religious tenets of any church, it is held that a member of the Spiritualist church, who combines faith and prayer with patent medicines compounded by himself, is not immune; the exemption giving him no authority to heal by agencies other than prayer or the practice of his religion.

On appeal from a conviction of the illegal practice of medicine the defendant had practised the religious tenets of his church. The court said if that was all that he had done he had acted within his rights; but it thought he had done more. On the stand the defendant characterized himself as a therapeutic and Spiritualist healer and dealer in patent medicines. He had patented them himself. He used a liniment, compounded of angle worms, turpentine, sweet oil, and benzine. He says that, while massaging the patient with this liniment, he indulged in silent prayer. He also prescribed for internal use a medicine compounded of wine, beef tea, and citrate of iron. The same medicine was used for every one. He argued that all this must be excused, because he had become a member of the Spiritualist church, and had been commissioned by that church as a spiritual healer. Some of the evidence which he offered on that subject was rejected. Enough was received, however, to prove that the church had recognized him as a healer, and that the practice of spiritual healing was a tenet of its faith.

The statute prohibits the practice of medicine without a license, but excepts from its prohibition "the practice of the religious tenets of any church." Public Health Law (Consol. Laws, c. 45) § 173. The Court of Appeals held in People v. Cole, 219 N. Y. 98, 113 N. E. 790, that the exception protected the practitioners of Christian Science, who taught as part of their religion the healing power of mind. Even then the court said that there were times when the question of their good faith must be submitted to a jury. But things were done by this defendant which no good faith could justify. He combined faith with patent medicine. If he invoked the power of spirit, he did not forget to prescribe his drugs. "It is beyond all question or dispute," said Voltaire, "that magic words and ceremonies are quite capable of most effectually destroying a whole flock of sheep, if the words be accompanied by a sufficient quantity of arsenic." Morley's Critical Miscellanies, III, p. 17. The law, in its protection of believers, has other cures in mind. The tenets to which it accords freedom, alike of practice and of profession, are not merely the tenets, but the religious tenets, of a church. The profession and the practice of the religion must be itself the cure. The sufferer's mind must be brought into submission to the infinite mind, and in this must be the healing. The operation of the power of spirit must be, not indirect and remote, but direct and immediate. If that were not so, a body of men who claimed divine inspiration might prescribe drugs and perform surgical operations under cover of the law. While the healer inculcates the faith of the church as a method of healing, he is immune. When he goes beyond that, puts his spiritual agencies aside, and takes up the agencies of the flesh, his immunity ceases. He is then competing with physicians on their own ground, using the same instrumentalities, and arrogating to himself the right to pursue the same methods, without the same training.

The meaning of the act is made plain when kindred legislation elsewhere are considered. In varying phrases immunity is granted to those who practice their religious tenets, but always in such a form as to confine the exemption to spiritual ministrations. The statutes are collated in the briefs in People v. Cole, supra. Thus, in Maine (Rev. St. 1903, c. 17, § 16; St. 1895, c. 170), Massachusetts (R. L. c. 76, § 9), and Connecticut (Gen. St. 1902, § 414), the exemption is specifically declared to extend to those who practice Christian Science. In New Hampshire (Laws 1915, c. 167, § 17), it is declared to extend to "those who endeavor to prevent or cure disease or suffering by spiritual means or prayer." In Illinois (Hurd's Rev. St. 1909, c. 91, § 11, p. 1474), the act does not apply to "any person who ministers to or treats the sick or suffering by mental or spiritual means, without the use of any drug or material remedy." Nearly the same language is used in the statutes of New Jersey (Laws 1915, c. 271, § 6), North Carolina (Laws 1903, c. 697), Colorado (Rev. St. 1908, § 6069), Virginia (Laws 1912, c. 237, § 11), and Michigan (Laws 1913, c. 368, § 8). There are like provisions in other states. Through all this legislation there runs a common purpose. The law exacts no license for ministration by prayer or by the power of religion. But one who heals by other agencies must have the training of the expert.

Assuming that to be the true view of the meaning of this statute, it was held that the defendant on his own confession had violated the law.—People vs. Vogelgesang, New York Court of Appeals, 116 N. E. 977.

License to Practice Osteopathy—Montana.—The Montana Supreme Court holds that Rev. Codes, §1605, including in its definition of practice of osteopathy all treatment by use of the hands or mechanical appliances, and so including the practice of chiropractics for the purpose of requiring qualifications and a license to practice, is not an attempt to confer a monopoly on the school of osteopathy. The court said that it is true that the statute defines the practice of osteopathy as a drugless treatment, because it is therein limited exclusively to treatment by use of the hands or mechanical appliances and requires acquaintance with the various sciences enumerated and the theory and practice according to the standards prescribed by recognized schools of osteopathy. But this does not give this school a monopoly of the practice. It leaves every person who in the judgment of the state board of osteopathic examiners has demonstrated that he possesses the knowledge and qualifications prescribed to engage in the practice and to earn his livelihood by this means. The legislation is not rendered objectionable by the fact that some persons choose to adopt another name and profess to belong to and to represent a different school. The statute merely discloses that one using the method of treatment therein described shall be deemed as practicing osteopathy, and that he must secure a license before he engages in the practice for compensation. If he does this, he has fully complied with the statute, and it is not material whether he chooses to style himself chiropractor or osteopath. In enacting the statute the Legislature was concerned about the qualifications which the practitioner must possess to the end that the public should be protected from fraud and imposition and not with the names of schools.—State v. Hopkins (Mont.) 166 Pac. 304.

Expert Evidence—Mortality Tables.—In an action for injuries a medical witness testified that from what he observed when he saw the plaintiff some months after the accident, and from what he observed from *x*-ray pictures, he should say the plaintiff was permanently injured. It was held that mortality tables were properly admitted in evidence over the objection that the plaintiff's injuries were not shown to be permanent.—Adamski v. Michigan Ry. Engineering Co., Michigan Supreme Court, 164 N. W. 402.

Prescribing Heroine—Physical Examination.—Under New York Public Health Law, §246, as added by Laws 1914, c. 363, and amended by Laws 1915, c. 327, providing that it shall be unlawful for any licensed physician to deliver any of certain drugs, except after a physical examination of any person for the treatment of disease, injury, or deformity, it is held that physicians, in treating narcotic drug addiction as a disease, need not make a physical examination of the patient each time the drug is delivered to him as a medicine; a physical examination enabling the physician to determine the amount of the drug a patient requires in his treatment from day to day, made within a reasonable time of delivery of the drug, is sufficient. A physician, who has the right to prescribe drugs in the treatment of disease, can deliver heroine to a messenger or agent for his patient, such as the patient's wife, without violating section 246; it being sufficient for the physician, under section 248, as added by Laws 1914, c. 363, and amended by Laws 1915, c. 327, to record the patient's name and also the name and address of the agent.—People v. Hoyt, 166 N. Y. Supp. 953.

Military Medicine.

NEW GERMAN GASES AND THEIR EFFECTS ON THE EYES.

For some months past, according to Teulière, in the *Journal de Médecine de Bordeaux* for November, 1917, the Germans have been employing some new gases in explosive shells. These are said to be tetrachloride of carbon and a chemical combination of sulphur, ammonia, and chlorine (the author terms it "bichloride of ammonium sulphide"). These gases are said to be heavy and colorless and to impregnate the earth. The majority compare the odor with that of mustard. The action is insidious, and is felt especially on moist surfaces, the effects being similar to chemical burns. Thus a perspiring man may be burned over the chest and in the armpits. In a particular case the track of a little rivulet of sweat, which had run down the abdomen to the scrotum, was burned, while the balance of the skin remained intact. Washing the face will start up the action of the gas. It is evident that the moist conjunctiva will be much exposed to such an action, although the gas is not of the so-called lacrymating or tear type. The lesions set up are of two grades of severity, benign and malignant. As soon as the shells have exploded there is an odor of mustard and a tingling of the eyes, to which little heed is paid. After a number of hours—ten in one case—an ocular reaction is in evidence—intense itching, marked redness of the conjunctiva, especially at the palpebral fissure. In the very benign case the condition goes no further. In others the conjunctiva becomes swollen, and chemosis may appear. The lids swell, and pus appears at the inner canthus. The iris is less affected than by the original gases, and dilates under atropine. There appears to be a very mild type of neuroretinitis. In the severe type of lesion the eye is as if burned by a corrosive mineral poison, the effects showing different degrees of intensity. The cornea may be directly burned and ulceration and hypopyon result. The depths of the eye do not appear to suffer in proportion from this type of burn.

During the use of the original gases the men were often unable to tell the source of the latter—whether gas wave or gas shell. In addition to the tear-producing type there were others which affected the eyes disastrously. The lacrymating gas caused the more violent initial manifestations, but otherwise the results were fairly constant. The author does not speculate on the nature of the older gases further than to imply that both asphyxiating and toxic forms could incidentally affect the eyes, while the lacrymating gases were used in the sole aim of temporarily blinding the adversary. While a destructive type of lesion does not seem to have resulted, the eyes often remained weak, and although decreased vision was at times complained of, due probably to a slight degree of neuroretinitis, the progress as regards ultimate recovery was favorable. The author states especially that he has never seen a case of permanent incapacity of the eyes from the older gases and that complete recovery has always occurred.

The newer gases are able in a certain percentage of cases not intimated by the author to cause destructive lesions of the conjunctiva and cornea, with resulting symblepharon, hypopyon, and corneal opacities, and in exceptional cases secondary iridocyclitis. The fundus does not appear to suffer in proportion, or more than under the action of the older gases.

METAL PROTECTION FOR THE SOLDIER'S HEART.

According to Filderman and Bonnette in the *Progrès Médical* for November 3, Delorme, the Inspector General of Army Surgeons, has strongly recommended to the Academy of Medicine of Paris the adoption of a cuirass for protecting the soldier from thoraco-abdominal injuries. It is not necessary that this cuirass be thick, for it is intended only to prevent injuries that are preventable. The idea is not new, for during the present war Adrian of helmet fame and others have made experiments with cuirasses. In December, 1915, 300 of the Daigre and Louppe models were tested, but their weight (20 and 26 lb. respectively) was so great that the soldiers did not use them. It was also objected that they were hard to get into, and once in place that they inhibited rapid and unforeseen movements. Adrian's cuirass was definitely called in in March, 1916. Like the other, it was too heavy and transformed the soldier into an ordinary porter. The idea of protection for the heart is radically different. Nearly every wound of this organ is fatal and many wounds are received therein. To protect the heart would be to give the man a chance for life. He would not, perhaps, succumb on the firing line but would go into the transportable class. If men have had their lives saved by such puny defenses as books and letters carried in a pocket which have served to deflect the bullet from a vital spot, should not some precaution of this sort be deliberately provided? It is on record that quite a number of articles of pocket wear have done this much for the wearer—pocket books containing letters or postals, a flexible book folded on itself, a watch, a cigarette case, a metallic mirror, a prayer book or testament, or a thick note book. The heart is in part protected by a natural grill, but the sum of defence is so poor that a bullet which could not break a finger might readily cause death. With the heart must be reckoned the great vascular trunks which communicate with it. This area is in the class with the cranial vault, the throat with its great vessels, and the spine.

In protecting the precordium we need only a light defence such as could be afforded by a disc of chrome-nickel steel 2 mm. thick. This disc can be cut in such a shape as to protect the heart and its great vessels and the weight will not much exceed a quarter of a pound. It should extend upward as far as possible without causing inconvenience. The disc should be enveloped in strong linen and fastened within the jacket. Naturally it is not symmetrical but covers the cardiac area and so is mostly to the left of the middle line. It lies to the left of the row of button holes and does not interfere with buttoning and unbuttoning the jacket. The defensive value of this shield is marked. Naturally, it cannot protect against rifle and machine gun bullets at close range, but is efficacious

against shrapnel bullets and the others on the rebound, and especially against small fragments of shells and grenades, also against revolver bullets when the range is not too close.

Treatment of Trench Feet and Allied Conditions by Passive Hyperemia.—Philip Turner applied Bier's method of treatment to cases of trench foot. In order to draw clear conclusions the cause of trenchfoot must be understood. It is thought by Smith, Ritchie, and Dawson to be essentially one of inflammation brought about by direct action of cold on the tissues, with histological changes chiefly in the blood-vessels of the affected parts and not due to any direct microbic action. They also point out that the essential difference between trench foot and true frost-bite is that in the latter the direct action of severe cold leads to the complete destruction of the vitality of more or less extensive masses of tissue, while in the former the effect of cold and wet, combined with certain factors which impede the circulation in the extremities, is to produce this inflammatory reaction. This is the generally accepted theory of these conditions. Turner offers his theory of the pathology of trench foot as follows: The condition is primarily caused by prolonged exposure to wet and cold, combined with other factors which impede the circulation. These set up the inflammatory changes described by Lorrain Smith. The vitality of the tissues is lowered to such an extent by this that septic organisms already present in or on the skin, possibly in fissures or excoriations, are enabled to set up more or less severe septic inflammatory processes resulting in the development of blisters, sloughs, and gangrenous areas. Needless to say, this view as to the part played by microorganisms is derived entirely from clinical observations, but some such explanation appears to be necessary to explain the more severe cases. This is a point of considerable importance, for if it is granted that septic organisms play an important part in the process, even though that part is secondary and indirect, their intervention must be taken into account in whatever line of treatment is adopted.

In his method of treatment prophylaxis is of the greatest importance, so that treatment must be directed to (a) cleansing of the foot and prevention of secondary infections, and (b) the treatment of the original inflammatory changes and also of any secondary infection which may have developed. For cleansing of the feet Turner uses ordinary soap and water, and the nails are cut and cleaned. The feet are then painted over with a solution of 1 per cent. picric acid in methylated spirit, and this application is repeated at first daily and later on alternate days. This solution penetrates the deeper layers of the epidermis and never causes dermatitis or irritation of the skin. The feet are then wrapped in sterile gauze and left exposed to the air until the patient finds they are more comfortable when covered by the bed-clothes. Bier's method is then applied.

As soon as the cleansing process has been carried out a constricting bandage is applied just above the knee. A Martin's elastic bandage cut in half provides a bandage of about the right length and strength. If this is not available, an elastic crepe bandage may be used, but these are not so satisfactory, as they stretch, and the pressure exerted may diminish or even disappear after a few hours. For the first day the bandage is kept on for 18 hours. It is then removed and reapplied after an interval of 6 hours. It is then again applied, and on the second and succeeding days is left on for 22 hours in every 24. The bandage should in all cases be applied just tightly enough to impede the venous return, but on no account must it obstruct the arterial supply. In many cases there will be no alteration in the appearance of the limb, but in some there will be noticed a slight increase in the swelling or the leg below the bandage may feel slightly warmer as the result of the congestion. The treatment should be painless and any complaint of pain—not slight discomfort—is an indication for the removal of the bandage. He only had one case in which this was necessary, and even here the bandage was subsequently reapplied without any further complaint of pain.

It has been pointed out that sometimes there is a temporary slight swelling of the leg below the bandage. This soon disappears, and in slight and moderate cases the swelling of the foot has usually quite disappeared in 24 or 48 hours. In severe cases it may persist for longer. Pain improves rapidly, and in 24 hours has either disappeared or has markedly diminished. Anesthesia improves steadily, but not so rapidly. In a moderate case with anesthesia of all the toes and of the greater part of the dorsum of the foot the sensation will probably be normal in four days, with the exception of blisters and gangrenous spots where the sensation is naturally still deficient. In cases of moderate severity blisters and the gangrenous areas shrivel, dry up, and eventually separate, leaving an unbroken delicate pink skin underneath. This process is very interesting, and not infrequently there is an extensive desquamation of the skin of the affected part, sometimes of practically the whole foot. In extensive cases, after the separation of dried blisters, gangrenous spots, and epithelial scales, there is left a surface of thin, pink, soft skin resembling a baby's foot. This is naturally very tender, and though the patient can walk in soft shoes, boots cannot be worn until the thin skin has become hardened and accustomed to pressure. He regards this desquamation and separation of dried gangrenous areas as part of the natural process of cure in these cases of moderate severity, and thinks that the treatment by passive hyperemia considerably accelerates the process.

When the symptoms have disappeared, usually after four or five days, the patient is allowed to walk in soft shoes; then after two days boots are worn, first for half an hour daily, and this time is increased until they can be worn two hours without discomfort, when the patient is discharged to the convalescent hospital. In moderate cases the procedure is the same, except a longer period is required for the same results. In fully 50 per cent of the cases, however, the feet are so tender that several weeks must elapse before the men can return to even light duty, rendering evacuation necessary. When the patients

are sufficiently convalescent to get up, Bier's treatment is still continued, the bandage being removed when they get up and is replaced when they return to bed, so that the bandage is applied 18 out of the 24 hours.

It may be asked whether the improvement in cases treated by Bier's method is really due to the Bier treatment and not to the rest, general treatment, and picric acid application. That it is due to the former is proved by the results in some cases where one foot has been severely, the other only slightly, affected. The bandage has only in these cases been tried for the severely affected foot, while the other treatment has been applied equally to both. In such cases one nearly always finds that the foot treated by Bier's method is in a couple of days better than the other more slightly affected foot, which has not been so treated. The treatment is simple and painless and requires no special apparatus beyond the bandage.

Red Cross Mission Is on Way to Italy.—The permanent Red Cross Commission for Italy is on its way to that country. The commission is in charge of Robert P. Perkins of New York. Dr. Joseph Collins of New York is a member of the commission. Upon its arrival the commission will take over the work which thus far has been under the direction of Major Murphy. The Red Cross War Council has just appropriated an additional $250,000 to meet Italian relief emergencies pending the arrival of the permanent commission, and Major Murphy has requested an additional $250,000 appropriation. Much work is to be done as the late Teutonic successes in Italy attended with their characteristic fiendishness, involved the destruction of a large number of military hospitals.

Ruling on Surgical Operations on Enlisted Men.—The Judge Advocate General of the Army has published a ruling upholding the right of an enlisted man to refuse to undergo a surgical operation unless the attending surgeon formally certifies that there is no danger to the life of the patient. This ruling is the result of trial by court martial of a private who refused to obey orders and upon conviction was sentenced to two months' imprisonment. It was found that no certificate stating that the proposed operation was devoid of danger had been filed and the prisoner was released. If the surgeon reports that an operation involves danger to the soldier's life and the man does not want to take the chance the army regulations prescribe that he must be honorably discharged from the army for disability.

Smallpox at Camp Meigs.—A report from Washington, under date of December 15, states that there are three cases of smallpox at Camp Meigs in the mechanical units of the Quarter Master's Corps. The camp is under quarantine. The medical officers do not regard the situation as serious or anticipate any spread of the disease.

Big Red Cross Drive.—A nation-wide campaign to increase the membership in the American Red Cross was begun on December 17 and will be continued until January 1. The end sought is the enrollment of 10,000,000 new members and the re-enrollment of the 5,000,000 old members. There will be an attempt made to increase the membership in Manhattan by 500,000 new members. The overhead cost for each new member is estimated at three cents, so if the goal for 10,000,000 new members is attained $9,700,000 will be added to the funds of the organization.

Jewish War Relief Fund.—Henry H. Rosenfeld, the assistant executive director of the American Jewish War Relief Committee, announces that the $10,000,000 fund for war relief pledged early in the year has been assured. Of the $5,000,000 which New York undertook to raise, $4,500,000 is in hand and it is estimated that New York's quota of $5,000,000 will be exceeded before the first of the year. Julius Rosenwald of Chicago will add $1,000,000 to the fund.

Summary of Health Conditions in Camps of the United States for Week Ending December 14, 1917.

1. *National Guard:* With the exception of the 34th, 35th, and 40th divisions, but few new cases of measles are reported from National Guard camps. In each of the divisions mentioned, with the exception of the 40th, the number of new cases is small as compared with the number reported for last week. In the 40th Division the number of new cases is 330, as compared with 279 for the previous week. Pneumonia following measles is also rapidly decreasing in amount in all but three of the divisions in which measles has been epidemic. In the three divisions referred to, 30th, 34th, 39th, an increase in the number of cases is noted, although the total number of new cases reported in each division is not high. For meningitis the number of new cases has increased in but two camps of the National Guard. The 35th Division reports 6 new cases as compared with 2 for the previous week, and the 30th Division reports 6 as compared with 1 for the previous week. The number of new cases reported in the 36th Division has decidedly decreased. The highest number of new cases reported in any other division of the National Guard is 3.

2. *National Army:* In the National Army a marked increase has occurred in the number of new cases of measles in the 87th and 90th Divisions, and a slight increase in the 89th Division. In all other divisions the number of new cases of measles reported is insignificant. Pneumonia conditions in all divisions of the National Army have decidedly improved during the week, except in the 90th Division, in which an increase of 36 new cases is reported over the report of last week. As regards meningitis, the 81st Division reports a marked increase in the number of new cases over the report of last week. The outbreak of this disease in the 89th Division continues to decline, but 8 new cases having been reported during the week. The highest number of new cases reported in other divisions of the National Army is 5. Seven divisions of the National Army report new cases of this disease during the week.

General Gorgas's Report on the Sanitary Condition of the Camps.—It is a painful revelation that Surgeon General Gorgas has made in his report on the various camps where the National Army is being trained to fight for the freedom of the world. Overcrowding, insufficient clothing, poor plumbing or none at all, hospitals without a water supply, the location of camps in centers of endemic meningitis—it all sounds most startlingly reminiscent of 1898.

RESTORING GASTROINTESTINAL CONTINUITY AFTER PARTIAL GASTRECTOMY.

THE treatment of cancer of the pyloric portion of the stomach has passed through many stages during the past fifteen years and has gradually become more and more radical under the influence of two factors: first, the newer diagnostic methods have led to earlier diagnosis, so that the operator has been afforded better and more numerous chances for the complete removal of the growth; second, there has been constant improvement in technique and in the types of operation employed. Years ago, when there was cancerous involvement of the pyloric portion of the stomach gastrostomy or gastroenterostomy was performed, no attempt being made to remove the diseased portion of the stomach.

Simple gastrostomy or gastroenterostomy has been followed successively by pylorectomy with end-to-end union of the partially closed large gastric opening to the cut end of the duodenum; pylorectomy with closure of both the duodenal and gastric openings and the restoration of gastrointestinal continuity by means of an independent posterior gastroenterostomy; partial gastrectomy with lateral anastomosis of the upper portion of the jejunum to the full length of the gastric opening, the jejunum being passed through a slit in the transverse mesocolon and after completion of the anastomosis the anastomotic area being brought through this opening and the edges of the mesocolic slit sutured around the line of anastomosis as in posterior gastroenterostomy (Pólya or Krönlein method); and finally we have an operation described by Balfour in *Surgery, Gynecology and Obstetrics* for November, 1917, an operation similar in many respects to the Pólya but in which the jejunal loop is carried in front of, rather than under, the transverse colon, as in the original Wölfler's anterior gastroenterostomy.

In this operation the pylorus, lymphatic glands, and a sufficient portion of the stomach are resected in the usual manner and the duodenal stump is cauterized and inverted. Balfour's description of the subsequent steps is as follows: "The first loop of the jejunum is procured and a point about 14 to 18 inches from the duodenojejunal angle is marked. The jejunum is then carried up in front of the transverse colon and omentum and a segment of suitable size is chosen at the point already marked. This section of jejunum is lightly grasped with rubber-covered forceps and directed so that the proximal end of the loop will be approximated to the lesser curvature of the stomach. A series of interrupted silk sutures in the serosa is used for the first line posteriorly, beginning at the greater curvature. All these sutures are placed before any are tied, and the ends of the top and bottom sutures may be conveniently left as guides. The first suture line is about one-half inch below the clamp on the cut end of the stomach, and on the side of the jejunum about three-fourths of an inch from the summit of the loop. * * * The jejunum is now incised * * * and the crushing clamp removed from the stomach. (If it has been possible at any previous stage in the operation to place without difficulty a straight rubber-covered clamp at a higher level on the stomach, soiling by unevacuated gastric contents will be prevented.) Any actively bleeding vessels are ligated. The posterior row of the anastomosis uniting the posterior wall of the stomach to the inner cut edge of the jejunum is of chromic catgut. The stitches on the gastric side should be taken after the edge which has been crushed by the clamp has been trimmed with scissors. A second row of finer catgut may be used to advantage in the posterior line. The first chromic catgut suture is continued in front in the usual way to complete the closure. An interrupted silk suture line similar to that used posteriorly is placed anteriorly, particular care being taken to reinforce the angle of anastomosis at the lesser curvature. A few interrupted silk sutures are placed where necessary to further protect the anterior suture line and the suture at the lesser curvature, the stump of gastrohepatic omentum which contains the ligated gastric artery being utilized as a support to the gastrojejunal angle at this point." Balfour says that the advantages of the antecolic end (gastric) to side (jejunum) method are quite obvious, that in their experience it can be used in practically every case, and that it is simpler, safer and can be accomplished in much less time than can any other method. A study of the statistics of partial reactions of the stomach for cancer at the Mayo Clinic would seem to warrant the opinion that there is less operative risk from this than from any other operation that has been employed in similar cases.

That this method is superior to the Pólya in all cases is open to question; but there can be no question of its superiority in unusually extensive resections and when the stomach segment remaining is high and relatively fixed, for in these cases it is often difficult to return the anastomosis through the slit in the mesocolon, and there is danger of angulation and obstruction in the jejunum under these conditions.

THE PATHOGENESIS OF HODGKIN'S DISEASE.

THE etiology of Hodgkin's disease still remains unsolved despite the efforts that have been made by some investigators to assign it irrevocably to the class of infective granulomata. The work of Bunting and Yates on the so-called *Corynebacterium granulomatosis maligni*, in relation to the disease, while interesting and suggestive, has not been universally accepted by pathologists owing to the fact that certain features are inadequately explained on the basis of a pure infective lesion. It is undoubtedly true that the disease exhibits, both clinically and pathologically, many of the earmarks of an inflammatory process; but it likewise displays characteristics which are usually associated with a neoplasm. For this reason it has been grouped by some pathologists with the leucemias and lymphosarcoma as a malignant growth of the lymphatic system. The occurrence of nodules in the spleen, liver, bone marrow, and elsewhere, certainly suggests analogy to a metastasizing tumor; and the fact that a fatal termination eventually results from widespread dissemination further emphasizes the malignant aspect of the disease.

The weak spot in the argument of those who champion the infective etiology is that diphtheroid bacilli are not peculiar to Hodgkin's disease, but are found in tuberculous glands, simple inflammatory hyperplasias, leucemic nodules, and also have been reported as contaminating organisms in routine cultures. Aside from these various distributions of the bacilli, acceptable evidence is still lacking of the production of the human homologue in animals.

Recently a new interpretation of the disease has been advanced by Symmers (*Archives of Internal Medicine*, June, 1917), based upon the microscopic study of material from 47 cases. Symmers approaches the problem from the strictly pathological standpoint, and postulates the theory that the histological changes in the lymph nodes, spleen, and other parts of the lymphatic apparatus, constitute a systemic process, with multiple foci of disease arising in different localities at approximately the same time in response to the same provocative agent. In other words, the fully developed Hodgkin's disease, although possessing a histology all its own, and maintaining in this regard an unmistakable individuality, nevertheless partakes of the nature of an infective granuloma on the one side and of a systemic lymphosarcomatosis on the other. The irregular type of temperature so frequently observed in patients afflicted with the disease is probably due to absorption of the products of necrosis, plus those derived from the more deliberate disintegration of cells. This explanation of the temperature is analogous to that usually offered for the fever so commonly observed in patients suffering from hypernephroma, in which variety of neoplasm, necrotic and degenerative changes are almost constant. The contention also finds confirmation in the negative evidence offered by the lymphoid tissues in lymphosarcomatosis, where necroses are uncommon and variations of temperature are correspondingly infrequent. Symmers hazards no opinion as to the nature and origin of the etiological agent, but says that whatever this may be it causes preliminary hyperplastic changes in the lymphoid tissues and initiates changes in the bone marrow, characterized among other things by proliferation of the non-granular mononuclear cells of the lymphocytic type, eosinophiles, and eosinophilic myelocytes. These cells, together with myeloplaxes, are thrown into the circulation and filtered out by the lymph nodes, or deposited in them in response to chemotactic attractions, the fibrotic changes in the recipient tissue representing a purely local reactive process. The histological abnormalities beyond the lymphoid system proper, namely, in the liver, kidneys, etc., represent a reaction on the part of normally existing lymphomatous foci to the same toxic substance which is responsible for the disturbances in the bone marrow and for the myeloid transformation of the lymph nodes.

RUFUS.

THE red-headed person has figured largely in folklore and has at one time or another been made the target of much banter, good natured and otherwise. It has been said fair-haired people in their evolution toward Addison's disease pass through a red-haired stage, though Leonard Williams, writing on the Real Dermatology in the *Medical Press* for Oct. 24, 1917, denies that there is any relationship between red hair and Addison's disease, and cannot even recall the occurrence of a case of Addison's disease in a red-headed individual. It is said to be a fact, however, that certain dark races dislike and distrust the occasional red-headed member of their own race, regarding him as in a certain sense a degenerate. Still, the red-headed member of a dark race may be subnormal through having lived for several generations in a climate which, failing to provide the stimulus of the sun necessary to the production of the pigment peculiar to his race, has also been lacking in the stimulus requisite for his development in other directions. He may be as Williams points out a "minus" among dark skins.

Now, the red-headed among fair skins is most distinctly not a minus. He is generally "a live wire" in all directions, he is very much more frequently a "plus" or overplus than a minus, and, as Williams says, "his great energies tend to be uncontrolled, his emotions to be violent, his imagination to be vivid, and his hopes sanguine."

There is a good deal of folk-lore in connection with the red headed in Europe. Red-headed women in France are said to smell of musk. In Wales a red-headed woman is said to have a peculiar odor when it rains. In Germany, they tag the red-head people with the unflattering appellation, "Rothe

Haar Gott bewahr"—red hair, have a care. In Great Britain the saying is "Ginger for Pluck." All of this goes to show that the red-headed man is not in a transition stage, but that he is eminently his own man.

The red headed are credited with greater resisting powers to disease than their brothers and sisters with hair of a less striking hue. In addition, it has been stated on the authority of an Edinburgh physician, by name Beddoe, that red-haired people are less liable by far to insanity than the ordinary ruck of humanity. Sir W. Arbuthnot Lane also holds that persons with red hair are much more resistant to diseases than the generality of people, and he has propounded the view that a disease becomes less virulent in type when it gains entrance into the body of a redhead than when it attacks a person with hair of a more modest color.

Evidence then is conclusive with regard to the great vigor of the red headed, but notwithstanding the possession of this driving quality by those of ruddy poll, few of the world's greatest men have been red headed. Gambetta, among statesmen and orators, is an example, and Frederick Barbarossa among soldiers. There may have been and probably were red heads among the great poets, but the only one which Williams can call to mind is Swinburne, who by the way was not physically vigorous, but erotic and even, in some respects, degenerate. Perhaps red-headed people are more greatly distinguished, as a rule, by physical vigor than by the possession of exceptional mental powers, although some among them have been, like Swinburne, endowed with genius.

SEROTHERAPY OF ACUTE POLIOMYELITIS.

NETTER was the first to make use of serotherapy for acute poliomyelitis. He simply injected the blood serum of convalescents into the tissues of sufferers from the disease, after Lævaditi had demonstrated that such serum actually contained an antibody which could neutralize the virus of the disease. At first the results were indecisive, but with cumulation of cases the efficacy of the treatment could not be disputed. Very recently Salanier, a former pupil of Netter, who became specially identified with cord studies, has summed up the technique and results of this form of treatment in a Paris thesis.

Serotherapy is really seroprophylaxis, and earliest diagnosis becomes a factor of great importance in treatment. Acute poliomyelitis can usually be recognized at an early period, but the earliest manifestations are often violent, a fact which does not seem to influence unfavorably the treatment. These abrupt symptoms refer chiefly to motor manifestations, but there is a sensory component in the evolution of the disease which may be recognized in regions not attacked by motor disturbances. When these sensory manifestations are in evidence they furnish an indication for prompt treatment with the expectation of benefit.

In a few cases serotherapy was practised before the appearance of paralysis, and apparently aborted the affection. But appearance of paralysis does not mean that it is too late for treatment. On the contrary, during any time within the first three or four days the treatment may be of value. The author has notes of 45 cases with the following results: 8 complete cures and 6 others classed as almost complete; 13 sensible ameliorations and 4 with appreciable improvement. As against these figures must be charged up 10 deaths from extension to the bulb and 4 cases in which treatment was of no avail. In a good number of cases the paralysis was checked, and in some cases there was involution. Quite characteristic was the rapidity of the cure as the injections were pushed. After the fourth, even after the third injection, certain subjects with initial paralysis were able to walk.

In the New York epidemic of 1916 the mortality was practically 29 per cent. In a total of 24,000 cases in the United States during the epidemic period some 400 were treated with convalescent serum, and the results were quite analogous to those controlled by the author. Antibodies form as early as the eleventh day (exceptionally much earlier) and have been known to persist in the blood for 30 years. From 200 to 300 c.c. of blood may be taken from a donor, and from 6 to 8 injections should be given, one each day. The average amount of serum injected should be 20 c.c. During the New York episode 9 gallons of convalescent blood were taken, which yielded 13 quarts of serum.

PERFORATIVE GASTRIC AND DUODENAL ULCERS.

DESPITE the fact that we have an enormous home material of gastric and duodenal ulcers it is not without interest to read what is transpiring in the same field in relatively remote parts of the world in which duodenal ulcer, at least, is far less common than with us. From a report of the activities of the Government and city hospitals at Wasa, Sweden (*Finska Läkaresällskapets Handlingar*, June, 1917), we learn that 35 operative cases of these accidents were treated during the period 1905-1916. Lindström, the surgeon who reports the material, states that but 8 of the cases were of duodenal ulcer, all of which occurred in males. Vomiting is by no means pathognomonic of perforative gastric ulcer for it was absent in 13 cases and constituted the initial symptom in but 3. On the other hand, disappearance of hepatic dullness is of notable diagnostic value, this symptom having been in evidence in 87 per cent. Operation was performed on every case and there were 19 cases of suture (fine silk interrupted) of the rupture. The ulcer was adherent in 7 cases. When suture was impossible a large tampon was applied and followed with gastroenterostomy. There were 25 primary gastroenterostomies, by the Hacker or Mayo technique, with 8 deaths. In two very bad cases Murphy's button was used. The author is a partisan of pri-

mary gastroenterostomy and has compiled records of 134 perforation cases by Swedish surgeons with 33 deaths, regarded by him as good work. The advantages of this intervention are dwelt upon, but the cases with unfavorable ending are not analyzed. In but one of the author's series was there a primary pylorus resection after Billroth's second method. The patient recovered. In peritonitis the exudate is mopped up and drainage reduced to a minimum. During the past two years he has not drained at the lower part of the abdomen.

In the author's own material the deaths amounted to 43 per cent.—considerably higher than that of the combined figures as given above. Nine patients died of peritonitis in the early days following operation. Of the 20 patients saved one has since died of heart disease with absence of stomach symptoms. Nineteen patients are known to have resumed their habitual occupations, although with the exception of two they had been unfit for work for years as a result of the ulcers. Sixteen have absolutely no gastric symptoms.

Responsibility for the Biopsy Outrage.

In reply to the protests of the medical press and of individual surgeons against the horrible biopsy scheme of the New York City Health Commissioner, the latter has claimed that he was acting under the advice and at the request of the Public Health Committee of the New York Academy of Medicine. That this was not so is now affirmed in a published summary of the activities of the committee for October and November, the paragraph relating to which reads as follows: "6. Biopsy.—The attention of the committee was called to the fact that its approval of establishing an additional service in the laboratory division of the Health Department for the examination of suspected pathological tissues is being interpreted as an endorsement by the committee of the indiscriminate use of biopsy. The committee has formulated a brief statement to the effect that the original endorsement of the Health Department's new service was not intended as an endorsement of biopsy." This disposes effectually of the commissioner's pretense of support by the Academy of Medicine and leaves upon his shoulders the sole responsibility for all the suffering that has resulted from his obstinate advocacy of this universally condemned practice.

Acute Nephritis Due to the Spirochæta Icterohæmorrhagica.

At the present time it is beginning to look as if the parasitism and pathogenicity of this spirochete may come to rival those of some of our best known pathogenic organisms, such, for example, as Eberth's bacillus, which is able to set up focal infections undiscoverable save through laboratory technique. Recently it occurred to Sisto (*Il Policlinico*, October 28) to make routine examination of the urine of healthy soldiers and soldiers with urinary and other disturbances for the presence of the spirochete, and in ten cases of acute hemorrhagic nephritis he obtained one positive find. In this case the malady was of a severe type, with marked edema and evidences of uremia. The sediment of the urine was centrifuged for a long time and stained with the Renaux-Wilmaers and Giemsa stains. The spirochete was present in great numbers and corresponded in all ways with the *S. icterohæmorrhagica*. That nephritis may complicate the usual type of spirochetosis is well known, and the opinion has long been current that the spirochete in question is perhaps responsible for some of the war nephritides. Recently two French authors recognized this organism in the urine of three patients with nephritis, so that the author can make no priority claims. In all of the four cases guinea-pig inoculation gave negative results, so that the question of virulence is still open.

Etiology of Typhus Fever.

The pioneer work by Plotz, Olitsky, and Baehr on typhus fever has been translated into German and was published by Urban and Schwarzenberg with date 1917. Probably this labor was undertaken and completed before the United States and Germany became enemies. The German translation is reviewed in the *Correspondenz-Blatt für Schweizer Aerzte* for October 27. The impression made upon the reviewer was favorable throughout, but so many microorganisms have been made responsible for this disease that one must be a little sceptical. Plotz first published his technique in 1914 and it is by no means difficult; yet no one seems to have taken the trouble to check up the work of the Americans; or at least no one has come out for or against the latter.

News of the Week.

Death Rate from Pneumonia Increases.—The largest number of cases of pneumonia for any week thus far this season was reached during the week ending December 15. Out of 1443 fatalities from all causes during the week 263 were due to pneumonia; during the preceding week, out of 1417 deaths 220 were caused by pneumonia. The normal number of deaths from pneumonia at this time of the year is about 200 per week. While there is always an increase in the number of deaths from respiratory diseases as the winter progresses, this year the increase began earlier than usual and has continued at a much higher rate. While the city and State health authorities think there is no cause to fear an epidemic, they have been active in warning the public that pneumonia is an infectious and communicable disease, and to a large extent avoidable.

Many Blinded in Halifax.—A telegram from Sir Frederick Fraser, superintendent of the School for the Blind in Halifax, states that more than 500 men, women, and children were blinded by glass from shattered windows in the recent disaster. The telegram asked that a press campaign be organized for the purpose of securing funds for relief work among the blind since at least half a million dollars was urgently needed and four additional buildings should be added to the School for the Blind.

Two Hospitals Incorporated.—At a special

meeting of the State Board of Charities on December 12, the applications for incorporation of the Carson C. Peck Memorial Hospital, Brooklyn, and the Mercy Hospital at Cazenova Park, Buffalo, were approved. Action was postponed on the applications for incorporation of the Hebrew Convalescent Home at 235 West 120th Street, and the institution planned by the Committee for the Care of Jewish tuberculous. The site for the Carson C. Peck Hospital is at Albany and Troy Avenues and Crown and Montgomery Streets. The building is in process of construction, and when complete, with its equipment, will cost $460,000.

Lack of Milk a Serious Menace.—The Children's Bureau of the Department of Labor reports increased suffering among young children as a result of the exorbitant price of milk and urges that aside from humanitarian considerations it will be a great economic loss to the country if lack of milk is allowed to impair the health of its future citizens. Cities in Pennsylvania, Maryland, and Delaware have found their milk supply problems so serious that the Governors' Tri-State Commission has recommended that the distribution of milk be regarded as a public utility and fair prices be assured. Conditions in New York, Philadelphia, and Chicago have not improved since cold weather has curtailed the milk supply.

Rockefeller Foundation Makes Annual Appropriations.—According to the financial budget of the Rockefeller Foundation more than $10,000,000 will be disbursed in war relief work and medical research. Of this sum $5,050,000 represents contributions to the Red Cross, the Y. M. C. A., and Y. W. C. A., the Jewish Camp Welfare Committee, the Training Camps Commission, and other organizations engaged in welfare work for the American armies in France. About $3,000,000 is to be spent in the work of the International Health Board and the Medical Board in China. These expenditures include $1,076,000 to be used in continuing the investigation of hookworm, yellow fever, and malaria, $424,000 for the Tuberculosis Mission in France, $918,000 for schools in Pekin and Shanghai, $627,657 for medical schools and hospitals in China, and $300,000 for instruction and research in medicine and public health in America, including instruction in mental hygiene.

Building Fund for People's Hospital.—A gift of $5,000 from Louis Kohenberg and $3,000 from a benefit theatrical performance have been added to the building fund of the People's Hospital. The new building for this institution is to be erected at Second Avenue and Thirteenth Street.

Obituary Notes.—Dr. HENRY C. WATT died suddenly at his home in Colorado Springs, Colo., on December 1, aged 45 years. Dr. Watt received his medical education in England and was licensed in London in 1895.

Dr. ADOLPHUS HENRY CARTER, for many years a practitioner of Salt Lake City, Utah, died at Wiggins, Col., about November 23, aged 67 years. He was a graduate of the Northwestern Medical College, St. Joseph, Mo., in 1892.

Dr. JOHN L. SULLIVAN of Passaic, N. J., died in Roosevelt Hospital, N. Y., following an operation, on December 1, aged 52 years. He was a graduate of the Albany Medical College in 1889, and took postgraduate courses in Berlin, Vienna, and Prague. He was a member of the Board of Governors of the Passaic General Hospital.

Dr. JULES F. VALLE, a graduate of Washington University Medical Department, St. Louis, died of heart disease, after a lingering illness, at his home in St. Louis, on November 24, aged 58 years.

Dr. RICHARD WEST BOURNE died at his home in Mexico, Mo., on November 21, aged 97 years. He was a graduate of Jefferson Medical College in 1845. He continued in active practice until a year ago.

Dr. STEPHEN HULL SEARS of Yarmouth, Mass., a graduate of Bellevue Hospital Medical College, in 1875, died on November 24, at the age of 67 years. He formerly resided in Newport, R. I., where he was acting assistant surgeon of the United States Marine Hospital Service.

Dr. DAVID CLEAVELAND GORDON, retired, formerly of Virginia, died in Washington, D. C., on December 1, aged 81 years.

Dr. GEORGE F. HOUSE, a graduate of the Indiana Medical College, in 1880, died as the result of paralysis at the home of his daughter in Clayton, Ind., at the age of 70 years. He was formerly president of the Clayton Board of Health and Charities.

Dr. JOHN F. MCCOOEY of Woonsocket, R. I., died of peritonitis following an operation for appendicitis at St. Vincent's Hospital, Worcester, Mass., on December 1, aged 37 years. He was a graduate of the College of Physicians and Surgeons, Baltimore, in 1903.

Dr. DAVID A. KINCAID, a graduate of Bowdoin Medical School, in 1878, died after a long illness at his home in South Portland, Me., aged 64 years.

Dr. JOHN P. LOGAN of DeWitt, Mo., died in St. Joseph's Hospital, Kansas City, on December 4, aged 64 years.

Dr. CHARLES S. PAYNE, a graduate of the Buffalo Medical College in 1884, died at his home in Liberty, N. Y., on December 12, aged 57 years.

Obituary.

RAMON GUITERAS, M.D., F.A.C.S.

NEW YORK.

DR. RAMON GUITERAS died at the French Hospital in this city on December 13 of meningitis, at the age of 57 years. He was a graduate of the Harvard Medical School in 1883, and was a member of the Medical Societies of the County and State of New York, the American Medical Association, the New York Academy of Medicine, the Rhode Island State Medical Society, the American Urological Association, and the New York Urological Society. He was a visiting surgeon to the Post-Graduate and Columbus Hospitals and consulting surgeon to the French and City Hospitals. Dr. Guiteras was a noted sportsman and had hunted large game in Africa and many other parts of the world. He was for many years secretary of the Pan-American Medical Congress, and he had also several times visited Cuba and other Latin-American countries on confidential missions for the United States Government.

Correspondence.

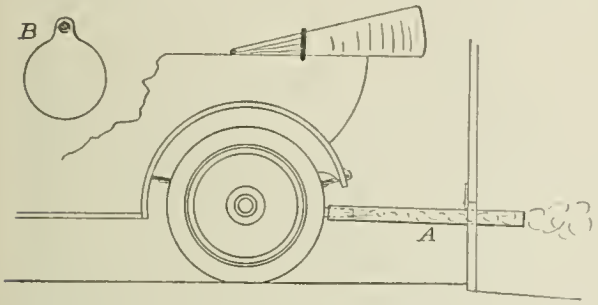
POISONOUS GASES IN A CLOSED GARAGE.

To the Editor of the Medical Record:

Sir:—The recent deaths from gas poisoning in a garage of Nat. M. Wills, the actor, and of Dr. Martin E. Benedict of Plainfield, N. J., emphasize most tragically the danger which exists under certain conditions.

The products of combustion in internal explosion motors, whether it be the carbon monoxide or other poisonous gases which they contain, have long been known to be acutely poisonous, and in certain cases fatal. Where these gases are exhausted into a confined space, such as the pit containing a pumping engine, or a small private garage, there is grave danger, unless precautions are carefully observed, of accidents such as the two cases mentioned.

The very general use of motor cars throughout the country has necessitated a great many small



A—Pipe in position. B—Pivoted cover for hole in door.

and inexpensive places for housing them. These are not usually heated, and it is generally necessary, in freezing weather, to run the engine of a car for a longer or shorter time before starting out. Of course, in very cold weather the temptation is to start the engine without opening the doors.

It has occurred to me that a very simple and inexpensive device will greatly reduce the danger, if not entirely eliminate it. The plan is to bore through the garage door, at a point about opposite the exhaust pipe of the car when in its usual position, a hole 2 or 3 inches in diameter, closed, when not in use, by a wooden drop-cover on the inside. A piece of light metal piping, of any kind, just large enough to be shoved over the end of the exhaust pipe of the car, is kept in the garage. When the car is to be started this pipe is first pushed out through the hole, and then drawn in and passed over the end of the exhaust pipe.

The diagram accompanying this will illustrate the idea better than words. W. C. Wood.

New York.

LETTER FROM CANADA.

(From an Occasional Correspondent.)

OPENING OF THE CONNAUGHT LABORATORIES OF THE UNIVERSITY OF TORONTO—FEEBLEMINDEDNESS IN ONTARIO—CANADIAN MEDICAL ASSOCIATION—ORTHOPEDIC WORK IN CANADA—ALBERTA MEDICAL ASSOCIATION.

Toronto, December 12, 1917.

The official opening of the Connaught Laboratories, which have been erected on a farm covering fifty acres of land presented by Colonel Albert Gooderham to the University of Toronto, for the purpose of research in preventive medicine and the preparation of serums and vaccines, took place on October 25 last. The ceremony was performed by His Excellency the Governor General of Canada. The occasion was an important one in Canadian medical annals, as it marks the establishment in the Dominion of an institute on the lines of such well-known foundations as the Pasteur, the Lister, and the Rockefeller institutes. The occasion will be remembered, also, by the pronouncement of the Premier of the Province of Ontario, Sir William Hearst, who announced on behalf of the provincial government that it was the intention next session to vote the sum of $75,000 to endow research in preventive medicine in the new laboratories, and that the income from this fund would be devoted entirely to research, since the laboratories themselves were self-supporting. Sir William also announced that a further sum of approximately $25,000 had been given for the same purpose, and that the income derived from this also would be expended in research work. The foundation, therefore, already amounts to about $100,000. A lecture on "War Activities of the Rockefeller Institute for Medical Research" was given by Dr. Simon Flexner, who outlined a few of the important contributions to science made by members of that institute.

The opening of the Connaught Laboratories completes the arrangements for research work commenced in May, 1914, when laboratories were established under the direction of Major Fitzgerald in the University of Toronto for the preparation of biological products, including diphtheria and tetanus antitoxin, antimeningitis serum, antirabic and smallpox vaccines. Arrangements were made by the Boards of Health of Ontario and Saskatchewan for the distribution through local boards of health, and at greatly reduced prices, of the vaccines prepared in these laboratories, and later on similar arrangements were made in other provinces. In February, 1916, a further step was taken by the Ontario Board of Health, which commenced to distribute free of charge throughout the province diphtheria antitoxin, tetanus antitoxin, meningitis serum, rabic vaccine, and smallpox vaccine. In view of the enormous demand for tetanus antitoxin for use among the troops, especially in Flanders, the work of the laboratories was increased by the addition of a special laboratory for the production of tetanus antitoxin, which was equipped by Colonel Gooderham, and established in 1915, under the direction of Dr. R. D. Defries. A grant of $5,000 was made at the time by the Canadian Department of Militia and Defense, on the condition that the entire output of antitoxin should be available for the use of the department, if required. At first, the work of preparing vaccines and serums was somewhat hampered by the lack of housing facilities for the animals required. The farm presented to the university by Colonel Gooderham, however, now makes it possible to continue the work under most satisfactory conditions.

An extensive inquiry into the practice of medicine in the Province of Ontario was recently conducted by Mr. Justice Hodgins. The Ontario Government has now appointed Mr. Justice Hodgins to investi-

gate the methods of dealing with the imbecile, the feebleminded, and the mentally defective in the province, with power to make suggestions which, in his opinion, will improve the present conditions. The prevalence of venereal diseases will also be considered, particularly in their relation to feeblemindedness.

It was decided at the Montreal meeting of the Canadian Medical Association that the 1918 meeting should be in Winnipeg, under the presidency of Dr. James McKenty of that city. It has been thought advisable, however, to make a change in this arrangement and to accept an invitation that has been received from the Ontario Medical Association to meet with them at Hamilton during the week commencing May 27, 1918. The occasion will be of unusual interest, as in addition to the Canadian Medical and the Ontario Medical Associations, the Canadian Public Health Association and the Canadian Association for the Prevention of Tuberculosis will meet at Hamilton during that week.

Some time ago an orthopedic hospital was established at North Toronto by the Military Hospitals Commission, which is in charge of all orthopedic work in connection with the Canadian Expeditionary Force. The hospital has accommodation for 440 in-patients and is equipped with all the necessary apparatus for the treatment of soldiers who have been incapacitated during the war. The work is under the immediate direction of Dr. Edward Bott. Individual attention is given to each case and, when necessary, a special appliance is devised or adapted to suit the requirements of a particular case. A device is attached to each appliance to enable the patient to measure his accomplishment, and this, it has been found, is a tremendous aid toward overcoming the natural depression of a man who has lost, temporarily at least, the use of a limb; the patient becomes interested in the progress he is making and is encouraged to put forth his best efforts. Records are kept of the progress of each case. A factory for the manufacture of artificial limbs has been established in connection with this hospital and a number of disabled men are being trained to make these limbs. Later on, when a number of men have been sufficiently trained in this work, it is possible that factories will be opened in other places. Various types of arms and legs are being manufactured and a new type of arm has been devised and is now being perfected by the commission; this, it is thought, will prove to be the most satisfactory kind of arm as yet manufactured. These limbs are supplied to soldiers by the Canadian Government and the cost of repairs, or renewal of a limb, will be borne by that Government as long as the man lives.

A school for masseurs and masseuses has been established in Hart House, which was erected on the campus of the University of Toronto by the Massey estate. This, in accordance with the wish of Lieut. Col. Vincent Massey, has been converted by the Hospitals Commission into a training center for workers in orthopedics and standard methods are being evolved there in accordance with recommendations made by Major R. Tait McKenzie, professor of physical therapy in the University of Pennsylvania, who recently made a survey of all Canadian military convalescent hospitals. Standardized equipment is being devised by workers at Hart House and arrangements for its manufacture have been made. Major McKenzie's work at Heaton Park Hospital, England, is already well known and the results he achieved are most encouraging: during the first six months of treatment by physical therapy, nearly 50 per cent. of the patients were able to return to the firing line and a further 30 per cent. were made fit for service at home or on the lines of communication.

In addition to orthopedic treatment, a disabled soldier is given vocational training while he is undergoing treatment and being fitted with the necessary limb. Training boards were established some time ago throughout the Dominion, with a personnel consisting of a medical officer, a vocational officer, and a third member who is *au courant* with industrial and commercial activities in that particular part of the country. The board is, therefore, in a position to form an opinion as to the man's capacity from a medical and vocational standpoint and the monetary possibilities as far as he is concerned in the various lines of work open to him. All this, together with the man's wishes and previous occupation, is taken into careful consideration, and whenever possible an occupation similar to that in which he was previously engaged is chosen, since it is difficult for an adult to take up successfully an entirely new kind of work in which he has to compete with men who have been doing it for years. As a rule the vocational training is commenced during convalescence and occupation has been found to be of the greatest benefit, no matter what the man is suffering from. By its means the patient is taken out of himself and his troubles and is given a new interest.

Convalescent hospitals have been established by the Military Hospitals Commission throughout the Dominion and at each of these equipment has been installed for the reeducation of physically disabled soldiers and those suffering from shock. A new hospital is in course of construction at Ste. Anne de Bellevue on a site adjacent to Macdonald College, on the banks of the Ottawa River, about twenty miles from Montreal. This will make it possible to take advantage of the splendid facilities for vocational training offered by Macdonald College, which includes a school of agriculture and a school of household science in addition to the Normal School for Teachers of the Province of Quebec. The plans are also being prepared for a military hospital which is to be constructed, on the lines of the Ontario Hospital at Orpington, in the County of Kent, England, in High Park, Toronto. This hospital will provide accommodation for one thousand patients. Hospitals are also being built at Kingston and London, Ontario.

The twelfth annual meeting of the Alberta Medical Association took place at Calgary on September 26 and 28, last. Among the questions that came up for discussion at that meeting was the prevalence of goiter in western Canada. In a symposium on the subject, Dr. Ritchie of Cochrane made certain statements which met with strong disapproval, and a resolution was passed by the association as representative of all the urban and rural districts of the province to the effect that goiter was not any more prevalent in Alberta than in any other part of Can-

ada, and that there was absolutely no reason for anxiety concerning the spread of the disease. Resolutions were passed also in favor of the establishment of a separate Government Department of Public Health with a competent deputy minister in charge, and in favor of an educational propaganda with a view to controlling and limiting the spread of venereal diseases. The presidential address was delivered by Dr. W. A. Lincoln of Calgary. The 1918 meeting will be held at Edmonton under the presidency of Prof. D. G. Revell of the chair of anatomy in the University of Alberta.

5. Speech Correction—A New Medical Study and a New Educational Movement.—Walter B. Swift gives a brief account of the work done under his supervision in the advancement of speech improvement, or correction, in the laryngological department of the Harvard Graduate School of Medicine. He has conducted graduate and undergraduate courses and the work has been arranged under four heads: medical, psychological, treatment, and educational. The medical courses consist in medical instruction, with special reference to speech. For example it is shown how enlarged tonsils interfere with early speech development, how cleft palate makes speech indistinct, how paralysis of the tongue muscles makes certain utterances impossible. The courses dealing with the psychological aspect take up the mental functions related to speech, considering their origins and the relations of eye and ear registrations of psychological interpretative processes and mental collaboration. Under the treatment aspect the courses take up the eradication of speech defects. The courses dealing with the educational aspect cover the relationship of speech disorder to the public schools. The educational aspect includes the training of the speech nurse. He further states that the more immediate aims of the two speech clinics in Boston are, first, to show teachers how to correct speech disorder in the public schools; second, to found other speech clinics under other medical heads; third, to establish other teaching centers as affiliated branches of the original home clinics. These Boston clinics are dominated by the research spirit. Every patient is fitted into some research problem. Every student is given an investigation. This accounts for the extraordinary productivity of the two clinics during the last few years. During last year about 120 papers were read by Swift and his assistants, and during the year before that 110. Yet they state that they have done nothing that others could not have done with the same training and opportunities. He tells that last year 103 teachers studied the methods and systems of the clinics, and now these methods are being put into practice in the public school systems of the various cities and classes will be formed for the correction of speech disorder under medical supervision. Physicians who have studied in these clinics have later established clinics of their own, affiliated with the home clinics, with aims of mutual aid. In carrying out the clinical method the patient's history is taken in the ordinary way and he is given a thorough examination — physical, mental, psychiatric, psychological, and educational — before the more exhaustive examination of the functions of his speech mechanism. Then treatment is outlined and he is drilled individually or in a class. At the same time he is fitted into an investigation and a minutely detailed record of progress is put down as data for some future use.

4. The Importance of an Antecedent State of Uneasiness as the Cause of Certain Normal and Abnormal Types of Behavior,—Meyer Solomon calls attention to the importance of states of "uneasiness" of varying intensity and duration which may be the basis of much that is apparently contradictory or not easily understood in the attitude of human beings. He describes this state of uneasiness as having an onset, or iniital stage, which culminates in a fastigium, acme, or height of the period of restlessness, only to be followed by the decline or disappearance of what may be called the attack. While the attack or period of uneasiness is on, the condition may be variously described by different persons. The individual feels restless, disturbed, under stress and strain and tension. There is a peculiar general state of uneasiness dominating the mind. Janet describes it as a feeling of incompleteness, of insufficiency; at other times it may seem, according to Adler, a feeling of inferiority, of insecurity, or of uncertainty. The feelings of strangeness may actually lead to dual or multiple personality. Solomon considers that the types described by Janet and Adler are to be found chiefly in the decidedly unstable and neuropathic persons. In the common forms this uneasy condition may be observed both in healthy persons as well as in patients. The person is ill at ease, fussy, cannot concentrate on the task before him, and is generally disturbed. While this state may be found in the most of humanity, it is not lasting and very infrequent, but in those in whom they occur they are often and prolonged and are a cause of much annoyance and trouble. In the really severe forms, occurring in so-called psychasthenia and in allied states of mental unrest, the attacks are so pronounced that they literally wreck the life of the person. The causes of this condition are legion. Among them may be named chronic ill health, in fact organic disease of any type, especially when of a generalized nature, so that it has its effect upon the nervous system, and hence more especially in organic diseases of the nervous system, such recurrent states are particularly apt to make their appearance. Also in the great physiological epochs, such as puberty and adolescence, pregnancy and puerperium, the menopause and the senium. Instability of the nervous system in individuals otherwise in good health, who have neuropathic constitutions or irritable nervous systems, which Adler would class as organ inferiorities. This irritability may be in the voluntary or involuntary nervous system or both. Persons suffering from epilepsy, vagotonia, migraine, hay fever, so-called true or genuine asthma, and the like are especially liable to these periods of unrest. Then comes actual suffering from some psychoneurotic or mild psychotic condition, such as those labeled neurasthenics, hysterics, psychasthenics, cyclothymics, and the like. Next there is met those with conscious mental conflicts of all types, financial problems, and kindred troubles. Then the individual with too little or too much to do, too much isolation, not enough rest, sleep, food, or relaxation will experience to some extent this "uneasiness." If the person is aware of the cause or causes of the trouble he often makes an attempt to handle it himself and obtain relief from himself through religion, or Christian Science, or quietude, or excitement. Men may seek all kinds of physical amusement, while others attempt to lose themselves in intellectual pursuits or to drive a hobby. Alcoholism may be the result of this state of "nerves," or gratification of the sexual passion may be the outcome. Solomon states that all this is of interest not merely from the purely scientific standpoint but it has a distinctly practical, therapeutic application. Where pathological avenues of escape have been entered upon,

or where domestic unhappiness, attacks of depression, and the like result from this condition, the therapeutic application is of the greatest importance. He considers that in some predisposed individuals outbreaks of the major psychoses begin in this way. Individualization must be the keynote, and a study of the particular person must be made carefully. The cause or causes of the uneasiness must be determined and removed if possible, and harmless or desirable, or even definitely helpful, means of attaining relief from the states of uneasiness substituted for any harmful habits that may have been established. Analysis and reeducation are thus in order while other psychotherapeutic methods may be of service in certain persons.

2. Wound Infection Among Lathe Workers.—Marvin D. Shie, while serving in the emergency hospital of a large manufacturing plant for a time, came in contact with such a large number of infections and cases of furunculosis that the matter claimed special notice. On some a pinprick, if left unattended, developed into a severe lymphangitis; a slight scratch in twelve hours into a linear mass of pus; a slight abrasion into a suppurating ulcer, and a laceration into a mass of necrotic tissue and pus. There were dozens of cases of multiple furunculosis, some patients developing as many as fifty boils at once on their arms and legs and faces. From fifty to sixty patients were seen daily, and of these from 8 to 10 per cent. had furunculosis, and 5 per cent. had wound infections of various sorts. When this was investigated further, it was discovered that of all the 1200 or more men in the machine shops, none had multiple furunculosis save those who worked on lathes, and furthermore that 90 per cent. of the infections occurred in men working on lathes. The new machine shop was given over to the manufacture of 8-inch shells, and housed about 400 lathes, while the old machine shop was used in the manufacture of machinery of various kinds, and housed only about twenty or thirty lathes. The cases of infections and furunculosis in these two shops varied directly as the number of lathes in each. As a result of an investigation into the situation, Shie reports that it was found that (1) In a large manufacturing plant the vast majority of cases of wound infections and furunculosis were found to be localized among lathe workers in the machine shops. (2) The peculiar features of lathe work are the use of cutting mixture and oil, and the manner in which these circulate and are used repeatedly, thus making them extremely liable to contamination. This contamination rendered them open to suspicion as factors in the causation of the wound infection and furunculosis. (3) These suspicions were borne out by bacteriologic investigation and animal inoculation, which showed the causative factor to be pyogenic organisms which were present in vast numbers in the cutting mixture and less numerous in the oil. Marked results were obtained. (4) Abundant portals of entry for these organisms were found on the arms of workingmen in innumerable small cuts and punctures made by flying chips of steel from the lathes. (5) The methods of prophylaxis possible are: (*a*) by heat; (*b*) by chemical disinfection, and (*c*) by a combination of the two. Various chemical disinfectants were tried, and the cresol group was found to be the most effective and the least expensive. (6) By use of chemical disinfection (cresols), wound infections have been reduced from 5 per cent. to less than 0.5 per cent. in the plant under consideration, and furunculosis has almost disappeared.

5. Perfusion of the Heart with Nicotine. D. T. Barry.

5. Perfusion of the Heart with Nicotine.—D. T. Barry has carried out experiments in order to investigate the action of nicotine on the heart, and has used the frog's heart for the work. The heart was systematically perfused with nicotine in varying strengths and a large number of observations made on more than 100 hearts of *Rana temporaria*. Some hundreds of graphic records were obtained. The results of these observations showed that nicotine in weak solution, 0.1 and 0.2 per cent., which has been neutralized, perfused through the hearts of frogs gives results which are fairly uniform, though certain variations occur. The first effect in a majority of instances is pure acceleration of the beat which is usually seen in less than half a minute from the introduction of the drug. This gives way to slowing, a phase in which increased force of the contractions is also seen. When acceleration is not in evidence increased force is usually exhibited alone within the first half of a minute, or both may occur together. The stimulation of accelerator fibers is soon followed by depression, and this double action is believed to be true of nicotine on the different elements responding to it. Slowing of the beat leads to a definite stop lasting one or a few minutes, but this is not common with solutions of less than 0.2 per cent. After a period of quiescence the heart resumes its beat with a rhythm which may be irregular or regular, the amplitude of contraction being usually greater than before. The contractions are now often reversed, viz., apex to base sequence, and this is more common after stronger solutions of nicotine, 0.5 to 1 per cent. With 0.5 to 1 per cent. solutions cessation of beat occurs sooner than with weaker solutions and lasts longer. With a solution of less than 1 per cent. it resumes beating spontaneously after arrest, with nicotine perfusion kept up, though this is not always so. The slowing of the beat and arrest for a while is due to stimulation of the vagus endings. The failure of atropine to counteract this points to stimulation of postganglionic fibers. This resembles its effect on the sympathetic side causing acceleration. The augmentor fibers are also stimulated by nicotine, and the succeeding depression is shortlived or may be much delayed. Evidence is given of their activity in certain stages of nicotine effect, when inhibitor

and purely accelerator factors seem to be suppressed. The activity of augmentor fibers to the ventricle seems to be possessed of a certain degree of independence, in consequence of which they may constitute the chief factor in independent ventricular rhythm. The work done by the heart can be increased by nicotine stimulation. This is in part nervous and in part muscular in origin. The delay in the passage of the contraction wave from auricles to ventricle is reduced by nicotine, in some instances independently of acceleration, and is frequently seen to lead to a reversed rhythm. The usually subordinate ventricle mechanism is stimulated to predominance in the cycle. Though all of the phenomena mentioned have been observed many times the only one which may be said to be unfailing in its appearance is slowing and arrest of the beat in proportion to the strength of nicotine used. Very strong doses of atropine do not abolish this.

3. Detection and Treatment with Emetine Bismuth Iodide of Amebic Dysentery Carriers Among Cases of Irritable Heart.—Margaret W. Jepps and J. C. Meakins in their report to the Medical Research Committee state that amebic dysentery was found to be either a direct or aggravating cause of irritable heart among soldiers returned from the Mediterranean Force. Their investigation was in the determination of cases of carriers among these soldiers and an attempt to cure them. From October, 1916, to February, 1917, an examination of the stools of all cases suffering from irritable heart from the Mediterranean Force admitted to the Hampstead Military Hospital was made, while no selection of men was made with reference to the presence or absence of a history of dysentery. Microscopic examinations of stools were made in the usual way and six careful examinations of at least each man was done before he was discharged as uninfected. Sixty-five cases were examined. The *Entamœba histolytica* was detected in twenty-four cases, the *Entamœba coli* in thirty-two cases, the *Lamblia intestinalis* in twenty cases, the *Chilomastix mesnili* in three cases, and the *Trichomonas hominis* in one case. The treatment by the use of emetine bismuth iodide was carried out by the employment of the drug in three different ways. When given in a powder this drug causes nausea and vomiting, so it was administered in tablet and pill form and was either mixed or coated with some material supposedly insoluble in the stomach. In all twenty-three courses of treatment were given with these preparations. No nausea or vomiting was produced, but in eight cases severe diarrhea and abdominal cramps occurred. Some looseness of the bowels was observed in all cases where the drug appeared to have any action. In the treatment with the stearine-coated tablets there were eight cures out of twelve cases treated, or 66 per cent. With the second, the stearine-coated pills with resin ointment basis, there were no cures, while with the third, another form of stearin coated tablets, there was only one cured out of four cases treated, or 25 per cent. Then the emetine bismuth iodide was given in cachets of 3 grains each to eleven cases. Ten cases, or 91 per cent., were cured after twelve daily doses. Jepps and Meakins found as the result of this detection and treatment that (1) additional infections with intestinal protozoa may be detected at the sixth and later examinations: (2) infections of *E. histolytica* in which no cysts measuring over 10μ in diameter are found in the stools are far from uncommon; (3) the use of emetine bismuth iodide has cured a large proportion (95 per cent.) of the amebic dysentery carriers; (4) the best method of administration of this drug is in the form of the loose powder in cachets in daily doses of 3 grains. At least 36 grains should be given in all; (5) symptoms of irritable heart in amebic dysentery carriers are reduced in a large number of those patients who have been cured of the amebic infection; (6) infection with intestinal protozoa has no marked effect on the differential leucocyte count.

La Presse Médicale.

October 11, 1917.

The Question of Bread, French Bread.—Legendre states that the subject of bread is the topic of the day in its twofold aspect—economical and agricultural. The wheat yield this year is between 30,000,000 and 40,000,000 quintals while from 90,000,000 to 95,000,000 are required to feed the people until the next harvest. There are not enough of other kinds of bread grain to make up this deficit. The wheat harvest of other countries are below the average. Imports of wheat and rice are uncertain because of the submarines, scarcity of ships and heavy freight charges. Unless some decided step is taken there will be no bread by the end of January, 1918. The measures to remedy this state of affairs include the following: Maximum extraction of the starch from wheat, addition to wheat flour of other flours, reduction of consumption to the minimum consistent with health, avoidance of waste in every form. All of these measures are of course already under way but are not as yet beyond criticism. Wheat comprises three parts, envelope, kernel and germ. The kernel consists of starch and gluten while the germ, rich in protein, has a food value at least equal to that of the kernel. A special layer of the germ beneath the envelope is rich in diastase. In theory the yield of starch should be 85 per cent. but as a matter of fact milling extracts only from 65 to 70 per cent. of white flour. The rest of the grain consists of a number of by-products—seconds, thirds, fine bran, coarse bran, each containing less and less starch. When wheat reaches the mill it is usually mixed with foreign substances—straw, dirt and other forms of debris along with portions of weeds. Rye may be ergotized, maize fermented. It is true that, thanks to modern milling, wheat is cleansed during the process, but only clean wheat should be milled. It is absurd to speak of the results of bolting without regard to the quality of the grain and the latter may be estimated by the weight of the crop for each hectolitre, which should average 74 kilograms. Wheat is made into three principal forms of bread, white, "brown" and whole wheat. Reckoning both nutritive value and cost "brown" bread should be superior to white bread while whole wheat bread should surpass brown bread. The utilization of whole wheat bread is about 88 per cent. Millers state that brown flour does not keep, bakers that it is hard to work with and consumers find it sour and unappetizing. Hygienists regard it as deleterious to the health (dyspepsia, eruptions) and economists state that it favors waste. In regard to the use of bran for cattle the Government is in the position of a farmer who owns only a calf and a small quantity of flour. In such a case the animal must make some other shift. A saying was once coined, "the bran gives the weight." Man needs the starch in the by-products of wheat and while the cattle may need these cellulose straw may be substituted. The recommendations of the author are much like those of Rubner. The wheat should be milled into flour and by-products and the seconds and thirds mixed with the flour in a ratio of 20 to 25 per cent.

October 22, 1917.

Tachyphylaxis and Its Role in Therapeutics.—Busquet refers to the original discovery in 1880 that an initial injection of peptone into a dog's vein rendered the blood incoagulable; but that after the blood had recovered further injections of protein no longer produced that result. Long afterwards it was learned that an injection of propeptone insufficient in itself to affect the blood sensibly protected the latter against the action of peptone even after an interval of but a few minutes. In 1911 Gley and Champy named this rapid immunization tachyphylaxis. Peptone is not the only substance to behave thus, for the same phenomenon may be produced with intestinal extract, placenta extract and in fact an entire series of such bodies. Attempts have

been made to explain the mechanism of this behavior as follows: As far back as 1883 it was known that blood coagulating substances when thrown into a vein produced their results instantly but that the blood once more became incoagulable because of the formation in the liver of antithrombine. Various experiments have shown that an anticoagulating substance, heriedine, can be made to immunize an animal against the toxic action of certain animal extracts. Various drugs used by the intravenous route are able to cause a tachyphylactic reaction. Here belong salvarsan, peptone, nucleinate of soda and chaulmoogra oil. A rabbit can be immunized against a poisonous dose of salvarsan by a preparatory injection, the principle involved being that of tachyphylaxis. In 1916 the author showed that while a first injection of sodium nucleinate in a dog's veins had a pronounced hypotensive action an injection five times as strong given after tension had become normal no longer produced hypotension. This phenomenon also appears to depend on tachyphylaxis. We have every right to believe that the latter readily occurs in mankind. Intolerance is often seen toward the first dose of salvarsan in syphilis, of nucleinate of soda in paresis, which is not encountered in later attempts. In regard to possible therapeutic applications we may first consider blood transfusion. Defibrinated blood is known to be toxic, even to the animal donor itself. This results from the action of the fibrin ferment in causing intravascular coagulation. This should be prevented by the injection of a small immunizing dose of blood. Next in order comes the intravenous exhibition of gland extracts. Might not a first injection immunize the subject against the therapeutic action of later injections? Probably not, for these glands have specific properties while their action as organ extracts is a general one, not at all specific. Suprarenal substance has a toxic action as an organ extract which immunizes against further injections. But this substance has nothing to do with the adrenaline and its vasoconstrictor action. The initial toxic action does not prejudice the use of the remedy—in fact by eliminating any further toxic action it distinctly favors it. Another class of remedies favorably influenced by tachyphylaxis comprises the colloids of the metals and metalloids.

Hygiea.

The Carrel Method of Wound Treatment.—Gramén tested this method with certain modifications of detail upon one hundred patients with suppurating processes in the Maria Hospital, Stockholm. The results generally speaking were good. In the treatment of appendicitis or other forms of intraperitoneal abscess the method was combined with the Mikulicz tamponade which was removed 1½ to 2 days after intervention. Afterwards ordinary irrigation was employed through drains inserted during the operation. Worthy of special mention is a case of empyema which was closed with sutures after Carrel treatment. As a result a pneumothorax rapidly decreased.

Contribution to Our Knowledge of Embolism and Thrombosis of the Mesenteric Vessels.—Hedlund reports two cases, the first being one of thromhosis of the superior mesenteric vein following operation for tubal abortion. She was seized with all the symptoms of ileus and a portion of the jejunum was resected. The only mechanical obstacle was an infarct in the intestinal wall which had narrowed the lumen of the bowel. The symptoms were not relieved and autopsy revealed the extension of the thrombotic process at the site of the resection. The second patient was seized with abdominal symptoms in the midst of an attack of pneumonia. Operation could not have been ventured. Autopsy revealed the presence of a liter of pus in the abdomen with fibrous adhesions. A section of the ileum (15 cm.) was gangrenous. There was arteriosclerosis of the superior mesenteric artery with extensive circulation disturbances in the corresponding mesentery.

Hydronephrosis with Old Blood Clots.—Gramén reports a case of successful operation for this condition, the cause of which was probably an accessory renal vessel which ran from the anterior aspect of the ureter to the anterior aspect of the lower pole of the kidney. The hydronephrosis sac contained a mass of rounded coagula the size of a small pea, evidently of different ages. The condition was beyond an explanation. Nothing resembling it could be found in literature.

An Exhaustion Phenomenon in the Areas of Sense of Smell and Taste.—Backmann made numerous experiments the basis of which was saturation of room air with some powerfully odoriferous substance. After subjects had been confined in the room for a stated interval the senses of smell and taste were tested for the same or other substances by Zwaardemaker's method, the concentration being progressively increased. A direct ratio was established between degree of exhaustion and concentration of test substance and even quantitatively there was marked agreement between the exhausting and the test perfume.

Correspondenz Blatt für Schweizer Aerzte.

October 20, 1917.

Indirect Trauma and Aneurysm of the Arteries of the Base of the Brain.—Hedinger has recently studied aneurysms in this locality with reference to certail pial and subpial hemorrhages. The aneurysms are chiefly the result of inflammatory processes and the rupture occurs by preference in the third decade of life, often in the midst of robust health. These arterial changes are with certain exceptions of syphilitic nature. Among these exceptions are cases due to indirect traumas, which even in sound arteries have led to sudden fatal hemorrhage. The author does not refer to free meningeal hemorrhage in these connections but to what he terms intrameningeal lesions, in which the blood escapes between the pia and arachmoid or beneath the former. The author describes a personal case in a woman of 47 with a bad personal history of disease (years of migraine, post typhoid thrombophlebitis of the lower extremities, removal of large uterine fibroma). She fell down an entire flight of stairs, bumping repeatedly her neck and shoulder which later pained her severely, giving rise to suspicion of linear fracture of a vertebra. She made a good recovery, save that her migrain caused a temporary return of these pains. After an intense spontaneous attack of the latter she was found dead in bed. At autopsy she was seen to be in good general condition. The uterus and adnexa had been removed. The left parietal bone showed a partial fissure. There was but little bloody fluid in the subarachnoid space but abundant fluid and clotted blood upon, within and beneath the pia. The basal arteries were abnormally fragile and a rupture was found in a wide sacciform dilatation in the left vertebral just before the branching point of the basilaris. A similar case is quoted from literature.

Commotion Psychosis.—Binswanger relates a series of cases of which one may serve as illustration. A soldier aged 25 of neuropathic stock (brother chorea, sister infantile paralysis) had been cured of gastric ulcer before the war. Mentally his record was fair, no imbecile reactions in association tests. Was of the affective type, cheerful and jolly, his occasional "jags" were not of pathological type. Very early in the war a bullet struck him beneath the eye. He was not stunned. Knew how to protect himself, was thought to be dead by his own men, but announced himself at roll call, weak and feverish. In the hospital he passed the first ten days in delirium with amnesia. Somatic and psychic states then rapidly came to equilibrium. Retrograde amnesia was present at first. The nature of this 10-day psychosis is obscure. As fever was considerable (maximum 38.88°) it could be imagined as febrile delirium. The alternatives would be commotion or exhaustion psychosis, the first from the impact of the bullet, the latter from the ordinary hardships of war acting upon a neuropathic soil. Eight months later, after an operation upon the wound, the temperature suddenly arose with a violent delirium which necessitated the use of the straitjacket. It was learned that patient had passed from the period of anesthesia directly into a psychotic state—that he had come out of the ether like a raving maniac. After the first 2 days he had lucid spells. The diagnosis was epileptoid excitation with delirium. It appeared he was 3 hours in coming out of the ether, which showed that his attack had really begun as a period of stupor. The subsequent history threw considerable light on the case, for without further psychosis the man developed severe cortical attacks between which he was chiefly out of sorts.

Book Reviews.

A Text-Book of Materia Medica for Nurses. Including Therapeutics and Toxicology. By George P. Paul, M.D., C.P.H. (Harvard) State Director, International Health Board, Rockefeller Foundation. Third Edition, Thoroughly Revised. 12mo of 295 Pages. Cloth, $1.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

This Materia Medica for Nurses has been written very carefully, and will serve as an excellent book for reference. It comprises a classification of drugs according to their action upon the various systems of the body—the drugs in this connection being mentioned by name only. Then in alphabetical order the drugs commonly used are given, with the various facts to be known well cited so that one can at a glance see the derivation, incompatibility, dosage, action, therapeutic indications, administration, pretoxic signs and toxicology.

To one teaching this subject, this arrangement necessitates a choice of teaching the drugs as they come in the alphabetical order with no grouping as to action, or of having the nurse look up each drug as it is studied. And it is very hard to impress them upon the memory unless some practical working classification is given.

Practical therapeutic measures and vaccine therapy are clearly discussed. Very good tables are arranged with drug dosage, the making of solutions, weights, equivalents, etc. Notwithstanding the difficulty of arrangement of material, the book answers the purpose for which it was written in a very satisfactory manner.

Diseases of the Skin. By Richard L. Sutton, M.D., Professor of Diseases of the Skin, University of Kansas School of Medicine; Former Chairman of the Dermatological Section of the American Medical Association; Member of the American Dermatological Association; Assistant Surgeon, United States Navy, Retired; Dermatologist to the Christian Church Hospital. With 833 Illustrations and Eight Colored Plates. Second Edition, Revised and Enlarged. St. Louis: C. V. Mosby Company, 1917.

In a review of the first edition of this work we expressed an appreciation of its excellence, pointing out a few omissions which a second edition would doubtless include. The author has added no less than 140 new illustrations, and the gross number of pages is increased by over one hundred. Most of the omissions noted by us have been incorporated, and there are other new topics, as well as revision of some of the old ones. We still believe that not enough attention is paid to the parasitism of the body louse in connection with typhus and other diseases. The literature of the subject is enormous, and a number of cuts would have been instructive, *e.g.* one of a "louse-proof suit."

The Book of Home Nursing. A Practical Guide for the Treatment of Sickness in the Home. By Frances Campbell (Mrs. George E. Campbell), Graduate of Hospital of St. Barnabas, Newark, N. J. Price, $1.00 net. New York: E. P. Dutton & Company, 1917.

Frances Campbell has written this book, not for the woman-dweller in the city where trained nurses are to be found on the other end of every telephone wire, but for the woman of the farm, town, and small city, who so often has to exercise her strength, judgment, and natural ability in the care of her sick without any technical knowledge to sustain her efforts.

The book is fairly alive with the spirit of the author,—a kindly, sensible, and keenly humorous spirit which must have brought a widening outlook and influence to the patients fortunate enough to have possessed its owner in the sick-room.

No attempt has been made to present the knowledge offered with any literary style. Because of the absence of all such effort, Frances Campbell just talks to one in a homey, confidential way, and soon one realizes that a mass of nursing facts have been presented and surrounded with a charm of interest, which bids fair to dispel any desire to remain in ignorance of such important knowledge. She carefully refrains from intruding on the physician's domain, and the chapter devoted to the care of children possesses especially valuable information.

Altogether this book deserves a wide circulation not only for the women for whom it is written, but for every woman, who in times of physical stress and sudden emergency, should have a clear understanding and knowledge of the means and methods of giving assistance in the restoration of the normal balance of health and strength.

St. Luke's Hospital Medical and Surgical Reports, Volume IV. 1917. New York: The Riess Publishing Company, 1917.

This volume of St. Luke's Hospital reports contains some valuable matter. Among the papers published therein are the treatment of uterine fibroids by Dr. Robert Abbe, Medical Treatment of Chronic Intestinal Stasis by Dr. W. A. Bastedo, Foreign Bodies in Giant Cells by Dr. F. C. Wood, and Blood Transfusion and Regeneration in Pernicious Anemia by Drs. K. M. Vogel and U. P. McCurdy. There are several excellent illustrations. A feature of the book is a description by Drs. F. C. Wood, Karl M. Vogel, and I. W. Famulener of the methods of laboratory technique employed at St. Luke's Hospital. The publication of these methods is a new departure in hospital reports and promises to be of great service to other laboratory workers as well as furnishing an example to be followed with profit by the editors of other volumes of this kind.

Everyman's Chemistry. The Chemist's Point of View and His Recent Work Told for the Layman. By Ellwood Hendrick. Price $2. New York: Harper & Brothers, 1917.

This is the second volume in the new "Modern Science Series," which is to be a collection of books presenting "the latest and most authoritative pictures of modern advance in scientific and sociological fields." If the projected series is to contain many books of the character of the one before us its success is assured from the start, for one seldom comes across a book dealing with a scientific subject, and dealing with it scientifically and authoritatively, in which the matter is presented in such a colloquial and humorous fashion as to keep the reader entertained while he is being instructed. Indeed the only objection we have to offer against the book is that one is so entertained by the style and manner of presentation of the subject that he is tempted to go on reading more than he can assimilate. And there is a great deal to assimilate, since the book covers in outline the whole of inorganic and organic chemistry from the composition of air and water to and through the fearfully compounded and cacophonously denominated coal-tar products. The author, though not a chemist by profession, is one by education, and enjoys a well-merited reputation among chemists for a broad knowledge that covers the entire field of that science. During the recent meeting of chemists in this city his accounts of the proceedings, published each day in the New York *Times*, were read and enjoyed by chemists and lay folk alike. The book which he has written is not a treatise on chemistry for the use of practical students of that profession, but is designed for the man in the street who wants to have a saving knowledge of chemistry without spending the time, which is not his to spend, in mastering the subject by studying dry text-books or blowing himself up in a laboratory. The author takes this man, thirsting for knowledge, aside and fills his mind with the solid facts of chemistry so camouflaged with humor and colloquialisms that the man thinks he has been enjoying an after-dinner chat and is surprised to find that he has really been to school and acquired a store of useful knowledge. The medical man of an older generation, whose chemical course consisted of a lecture three days in the week during one college term, and this lecture the last one of the day when everyone was tired and sleepy, will find this book exactly what he needs to make up for his deficiencies and to give him a nodding acquaintance with a science without some knowledge of which much that he reads in his journals and medical books is almost unintelligible. The book should be read a chapter at a time, a task which will prove to be a pleasure, the temptation to skim along rapidly in order to enjoy the author's jolly style being stoutly resisted. If he does this, when he closes the book he will have the immense satisfaction of feeling that at last he understands something of one of the most interesting, and still most mysterious, of all the branches of learning revealed to mortal man.

Medical Bacteriology. By John A. Roddy, M.D., Associate in Hygiene and Bacteriology, Jefferson Medical College; Chief Assistant, Department of Clinical Medicine, Jefferson Hospital; Professor of Hygiene and Bacteriology, Philadelphia College of Pharmacy; sometime Serologist to the Philadelphia General Hospital, etc. With 46 Illustrations, of which eight are printed in colors. Price, $2.50. Philadelphia: P. Blakiston's Son & Co., 1917.

Something over one-half of this book is devoted to a description of bacteria and the techniques for their demonstration. This section would rank with first or second year undergraduate textbooks or even among those of a preparatory course for medical studies. The second section, on the other hand, belongs under diagnosis and therapeutics, and hence to the last two years of the medical curriculum and to postgraduate study. The author, however, does not in his preface claim that the book was written with this end in view. On the other hand, he is very modest in his estimate of what his work should accomplish. But few volumes are so planned that they will be of service for so many years of student life. With this end in view the book should perhaps have been larger.

The Principles and Practice of Dermatology. By William Allen Pusey, A.M., M.D. Professor of Dermatology in the University of Illinois, Emeritus, etc., etc. With 54 Plates and 466 Illustrations. Third Edition. New York and London: D. Appleton & Co., 1917.

This edition contains over 10 per cent. more matter than the preceding one which appeared in 1911, but this is accounted for in part by a 20 per cent. increase in the text figures. The author enumerates 26 new subjects which are incorporated into this edition. When writing of subjects of which he is conversant Dr. Pusey has no superior; but in matter which has to be borrowed he is sometimes unfortunate, as when he states that espundia is incurable. Escomel, who first described this condition, cures it with antimony. The readers of this book also are entitled to a more accurate sketch of the history of syphilis. Professional historians and scholars do not accept the American origin of the disease; Sudhoff and the expressions of opinion of Osler and Garrison, for example, are adverse to this view. The credulity of physicians was never better shown than when they fell (so to speak) for Block's frame-up (to quote Dr. Downing). Those, however, are minor faults, or rather blemishes, and really do not detract from the excellence of the work as an authoritative guide to the practice of dermatology.

Surgical Contributions from 1881-1916. By Rutherford Morison, M.B., F.R.C.S. Edin., F.R.C.S. Eng. Consulting Surgeon Royal Victoria Infirmary, Newcastle-on-Tyne; Professor of Surgery, Durham University, etc. Volume I. General Surgery. Vol. II. Abdominal Surgery. Price, $10 per set. New York: William Wood and Company, 1917.

Volume I. contains 31 reprinted articles which appeared originally in various British medical periodicals. The text is accompanied by 41 plates. The work is dedicated to the author's former house surgeons whose photographs in miniature face the title pages. These number 32. The papers have a wide range and quite a few are general in scope, while six have to do with affections of the extremities, three with surgery of the blood vessels, while the balance are pretty well scattered. Of great interest to American readers are accounts of surgical visitations to the United States in 1892 and again in 1914.

Volume II. is much larger than the first of the set, since it contains 953 pages. It comprises 36 reprinted papers, some of which are very long. The two papers on intestinal obstruction aggregate about 100 pages. Many of the articles are general in scope but there are special papers on diseased uterine adnexa, strangulated hernia, hysterectomy, appendicitis, gallstones, operative cure of ascites, deciduoma malignum, pelvic surgery, gastric and duodenal ulcer, general septic peritonitis, surgery of the colon, etc., etc. In combining what is known as "straight surgery" with major operative gynecology Dr. Morison suggests Lawson Tait of other days and Howard Kelly among contemporaries, not to speak of numerous others, past and present.

Pharmacology and Therapeutics for Students and Practitioners of Medicine. By Horatio C. Wood, Jr., M.D., Professor of Pharmacology and Therapeutics in the University of Pennsylvania; Second Vice-chairman of the Committee of Revision of the U. S. Pharmacœpia. Second Edition. Price. $4.00. Philadelphia and London: J. B. Lippincott Company, 1916.

This second edition of Dr. Wood's comprehensive work brings the material offered up to the present standard, especially all drugs in which there has been gained a rapid advance of scientific knowledge. The articles on veronal, digitalis, pituitary, salvarsan, etc., have been practically rewritten, while twenty or more drugs not included in the first edition have been added, such as apiol, chrysarobin, homatropine, aspidosperma, etc.

Dr. Wood states that he has also introduced into this volume one innovation which the U. S. Pharmacœpia has adopted from the British, that is the term "mil" for the thousandth part of a liter. He explains that this is a much more convenient and accurate term than the "c.c." previously used.

This work is contained in nine chapters, beginning with preliminary considerations, then taking up in the order given the following: Drugs used to affect secretion, drugs used to affect nervous system, drugs used to affect circulation, drugs used to affect the alimentary tract, drugs affecting metabolic processes, drugs acting on causes of disease, extraneous remedies, and concluding with drugs of minor importance.

Every physician, pharmacist, and student knows how difficult it is to acquire a delight for the study of drugs, unless the taste is inborn. This the author has largely overcome by the manner in which he has presented his material. Simple, direct, with not a word more than is necessary to provide grace and coherence to his style, Dr. Wood has lived up to the reputation already established by the older members of a family famed for its charm of utterance and keen insight into all things scientifically medical.

Rational Sex Ethics. A Physiological and Psychological Study of the Sex Lives of Normal Men and Women, with Suggestions for a Rational Sex Hygiene. W. F. Robie. A.B., M.D., Superintendent Pine Terrace, Baldwinville, Mass. Sometime Fellow at Clark University. Boston: Richard G. Badger; Toronto: The Copp Clark Co., Limited.

A work of this type and character is always a difficult one to discuss, for the reason that it has to be studied from so many different viewpoints. This book, however, is valuable because of three distinct reasons: First, the material offered has been obtained from practically normal people; second, this same material has been thoroughly studied, digested, and then presented to readers absolutely divorced from any suggestion of hysteria or emotionalism; and third, the author has written in a healthy, sane, direct manner, placing sex ethics on a purely natural basis.

One other point which demands considerable notice is the fact that, not having taken the woman's point of view as to her sex life chiefly from hearsay or from that which hysterical patients might tell under the influence of a physician's presence and dominance, the author has obtained the history of a woman's normal sexual balance from a healthy woman herself—his wife.

Whether all readers will agree to work out these absorbing problems to the same conclusions that the author has done is a matter of little importance. The important fact is that Dr. Robie has offered a light along that path which all must tread, and whether it is trod in decency and in order according to the present day viewpoint, will depend much on the amount of education in sex matters the individual has obtained, aside from the natural will-power possessed as well as moral obligation to be considered.

Each crystal of truth regarding the fundamental basis of life, sex, but adds to a noble working out of the germ of all life, sex. Dr. Robie has offered his part in the solution in a splendid, high-minded, broad-spirited way, that should go far towards placing sex ethics on a rational basis.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Eleventh Annual Meeting, Held in Memphis, Tenn., November 12-15, 1917.

(*Concluded from page* 1050)

SECTION ON PUBLIC HEALTH.

CHAIRMAN, DR. ARTHUR T. MCCORMACK OF BOWLING GREEN, KENTUCKY.

Popularizing Public Health.—Drs. C. E. TERRY and F. SCHNEIDER, JR., of New York City, stated that one of the first ways in which health officers felt the disturbing influence of the war upon disease prevention organization was with regard to public health nurses. With the creation of an American army abroad a large military nursing service had to be created with great haste. The Red Cross issued a call to its nurses. Among those responding were many public health nurses, women doing infant mortality, tuberculosis, and contagious diseases work in our cities. The withdrawal of these nurses produced a seriously acute situation. The matter came to a head and the mature judgment of the authorities was that public health nurses would be more useful left in their existing occupations. The Red Cross went further than this. Seeing the special importance of public health work in war time, the organization turned over eight nurses to the State Department of Health in Massachusetts, these women to be employed on new child conservation work. In the saturation and resaturation of our public with a realization of health truths, and with a knowledge of the importance of health work, the family magazine had unparalleled possibilities. In addition to the magazine stories, the Seventh Baby Campaign had pushed this experiment in constructive journalism a step further. A field force of trained and experienced public health nurses had been assembled, and two traveling laboratories with experienced laboratory men had been provided. This field force was now engaged in making surveys of infant mortality in particular, and public health work in general, in communities between 10,000 and 40,000 population throughout the country. Careful inventories of local conditions were made, and reports were submitted giving findings and outlining a practical program for public health progress. The field work was conducted only upon the request of local authorities, and with their cooperation. The subjects covered were infant mortality in particular, that is, the number and causes of infant deaths and existing efforts to prevent them; milk supply, water supply, sewers, and sewage disposal, privies and fly-breeding, waste disposal, and organization and budget of the health department.

Distribution of Vaccines and Serums by the State.—Dr. C. A. SHORE of Raleigh, North Carolina, stated that diagnostic work was most useful when done near to the patient, and therefore the establishment of municipal laboratories was always to be encouraged where practicable. In his own state of North Carolina they had no great cities, but a large number of flourishing and prosperous communities with a population between 20,000 and 40,000. Each of these little cities, and many of the counties, should have their own laboratory for diagnostic purposes and for the control of its water and milk supplies. The State Laboratory should serve the sections not otherwise provided for, and in addition should have a much wider field of usefulness and a direct public health service in making and distributing those vaccines and serums which had been accepted as reliable, curative, or prophylactic agents. The next work taken up in their laboratory was the distribution of typhoid vaccine. This was given free to all registered physicians, and they had been sending out annually for three years an average of 400,000 doses. They estimated that at least 100,000 citizens were immunized against typhoid fever each year. He believed in the free distribution of diphtheria antitoxin. It was only then that we could hope for its use in all cases of diphtheria.

Intensive Community Work in Tennessee.—Dr. E. L. BISHOP of Nashville stated that health had been said by some one to be the physiological functioning of a community. Class education was of importance in that we hoped to reach the masses through the masses. Of the latter the family physician was of as much if not more value than any other factor. No one expected him to be a trained sanitarian, but where postgraduate work was offered him in a practicable way he would form an important link in our chain of education. He believed it also to be a part of the field man's duty to attend all county medical society meetings during his stay, to secure their endorsement, and to take part actively in each meeting where opportunity offered. He would always be made room for. Special attention should also be paid to any social service organization or club of like nature. We should try to secure organized effort from a community standpoint, and to establish such a sanitary sense that health work would ever afterwards be seen as an affair of community interest, and not through the tubular vision of the individual perspective. Unless this be done, no matter how well the result showed on paper, we would have fallen short in attainment and would have secured but temporary improvement.

Health Education in Rural Districts.—Dr. L. A. RISE of Columbia, South Carolina, said that two counties in South Carolina this year had been induced to appropriate money through the legislature for a campaign for better health in their rural districts. Notwithstanding the phenomenal rise in the price and scarcity of labor and material in his State, they had been able to make a fair showing, and to stir up an enthusiasm for civic betterment along the line of disease prevention which would cause a demand on the part of the rural population in these counties for a continuation of this work next year. They had largely stressed the prevention of intestinal diseases by approved methods of sanitation, but they had also devoted a part of their work to the prevention of tuberculosis, and diseases of childhood. Lectures in schools, both negro and white, had been given in practically every community. In his county and community fairs they had had health exhibits which had taught valuable lessons in disease prevention to thousands.

Medical Inspection of Schools in North Carolina.—Dr. GEORGE M. COOPER of Raleigh, North Carolina, said that the purpose of medical inspection was two-fold: (1) To inculcate a knowledge of hygiene and sanitation in the minds of the children at an impressionable age. That was teaching applied hygiene. (2) To discover the children who had preventable or curable defects, and to have the trouble treated before permanent danger occurred. The problem in a nutshell was to find the defective children and get them treated. Twenty per cent. of all the money expended for education in the United States was wasted, according to the United States Public Health Service and the National Educational Association, because of preventable physical defects of the children. This meant an annual loss of millions of dollars. About one-fourth of all the men examined thus far for the National army under the draft law had been rejected on account of physical defects. Of the rejections more than one-half had been due to the easily preventable conditions if treated not later than the early years of school age. These defects included eye, ear, throat, and teeth troubles. For the purpose of aiding in the treatment of all children whose parents were financially unable to procure the service, the State Board of Health had a fund of $10,000 per year available, matched dollar for dollar by the counties, thus constituting a fund of $20,000 per year for this purpose. If every teacher and every medical inspector did his or her full duty in a sympathetic manner, numbers of children would have the benefit of first-class dental and specialists' services who would otherwise never get it.

The Relative Value of the Public Health Nurse in the Solution of the Tuberculosis Problem.—Dr. W. L. HEIZER of Frankfort, Kentucky, stated that the chief advantages of starting a health campaign in a county, which had done little before, by employing competent public health nurses, were: the natural inclination of a community to spend a less amount of money, a false economy, to accomplish a public service; the popular appeal to the public by the ministrations to the sick;

the prenatal care in selected cases; a quick appreciation of the value of public health work by reason of its publicity secured as result of appeals for aid to churches, fraternal roganizations, the city and county government; when a nurse was employed by a county health and welfare league, as was the policy of his commission, or a similar organization with a large county membership, it was a logical and certain means of crystallizing such an awakened public health sentiment to the formation of a permanent county, city or state health department with efficient officers and sufficient equipment and assistance, to make real work permanent, constructive and effective.

The Normal College as a Factor in the Dissemination of Public Health Knowledge in the South.—Dr. U. F. JONES of Hattiesburg, Mississippi, asked what could be done to bring about a closer relation between the health department to make the knowledge and practice of public health a part of the everyday life of a community, and to conserve the loss in a community due to preventable disease? The school was the agency endowed by every circumstance for the accomplishment of the task. The normal schools were among the few largest factors in the educational scheme of his county. The normal school was not doing justice in training its teachers in health work unless it had a clinic for the diagnosis of such defects as they would constantly find in their own schoolrooms, clinics showing defective teeth and large tonsils, malnutrition, defective vision, etc., physical defects which should be remedied during school life.

Physical Status of Juvenile Delinquents.—Drs. ELIZABETH BASS and MAUD LOEBER of New Orleans gave this paper, which was based upon clinical and physical examinations of children in the reformatories of New Orleans. They said that many of the children who were sent to reformatories would make better men and women if even superficial attention were given to them before their commitment by a physician attached to the juvenile court, to be followed up in each instance, according to the opinion of the court, either by the child's natural or rightful guardian, or should the court deem commitment proper, by the custodian of the municipal or state institution. Their suggestions, therefore, would be: (1) A conscientious routine physical and clinical examination, with recommendations on the case to the court before commitment. (2) Penalty exacted of the natural guardian in cases of neglect to care for the physical defects of the child or children in their care. (3) Physical and clinical records kept of each child at the time of admission into reformatory, and observations recorded once each month thereafter, or more frequently, should the case require it. (4) Each reformatory attending physician should have as his assistants specialists in the various branches of medicine, as staff officers, to regularly visit and treat cases needing attention in his specialty. (5) A resident trained nurse. (6) That the diet and mode of life in an institution be passed upon by that institution's attending physician.

Dr. OSCAR DOWLING of Shreveport, La., said that the prison system in vogue was an insult to our intelligence and a disgrace to our civilization, which we called Christian, and there was no feature of the whole system more in need of reform than that which pertained to the juvenile criminal. Although not complete, there were sufficient data to show the close and intimate relation of mental states to abnormal physical conditions. That some defect or bodily pain was the cause of actions often mistakenly called criminal was clear. Then, logically, the cause should be discovered and the remedy applied. Every court should take cognizance of pain or mental defect as a predisposing cause of crime. No jury would convict an insane person. Institutional life at its best for the well was not an environment which gave ideal results, and life in an institution for the physically defective, even with the utmost vigilance, could not be other than trying in the extreme. He heartily approved the recommendations contained in the paper, each one of which was important and imperative. He believed they were practical and could be put into immediate effect wherever public opinion would make the demand. He believed full publicity as to the details of juvenile court proceedings and institutional life would stimulate public sentiment to the degree that the demand would be made.

SECTION ON MEDICINE.

CHAIRMAN, DR. J. S. MCLESTER OF BIRMINGHAM, ALA.

Chairman's Address: Chemical Analysis of the Blood as an Index to Treatment. — Dr. JAMES S. MCLESTER of Birmingham, Ala., said that the question was frequently asked, did the chemical analysis of the blood, which was of admitted interest in the research laboratory, offer anything of real practical value to the clinic? Unquestionably it did. One needed only to point to nephritis and diabetes. But of still greater importance was the wonderful field for clinical research which had thus been opened, and when he considered the possibilities through these methods of solving old problems and gaining insight into new things, he was tempted to say that as yet the surface had hardly been scratched. But what of its value to the clinic today? The non-protein-nitrogen of the blood in which was included all nitrogenous waste products, was increased with loss of kidney efficiency. The kidneys determined the height of the waste products in the blood and, conversely, the accumulation of such waste products gave evidence of loss of kidney function. Diet was normally of no influence since independently of protein intake the non-protein-nitrogen maintained a fairly constant level, but with diseased kidneys the diet became a determining factor and a high non-protein-nitrogen content of the blood could usually be reduced by proper feeding. Estimations of the non-protein nitrogen alone, however, were of small clinical value, serving as they did chiefly as a basis upon which other values might be reckoned. Urea formed in health about one-half of the non-protein nitrogen, the upper values of each being approximately 15 and 30 mgm. respectively, in 100 gm. of blood. With the increased non-protein nitrogen of kidney incompetency he found a relatively greater increase of urea, so that with 50 mgm. of non-protein nitrogen, for instance, we were likely to find 30 or 35 mgm. of urea. A consideration of these figures, and particularly of the change produced in them by appropriate diet, gave information which was of definite clinical value; but Ambard's coefficient, which was intended to express by mathematical formulæ the mutual relationship of blood urea and urine urea, was coming to be regarded as an unnecessarily complex piece of reckoning. Attention had frequently been called to the increase in blood uric acid which accompanied chronic interstitial nephritis, this increase being parallel with that of the other waste products. Recently Myers and Fine had reported a number of cases of early chronic interstitial nephritis showing increase of blood uric acid with no corresponding accumulation of urea and creatinin and little or no disturbance of phthalein output. They expressed the opinion that an increase in the blood uric acid alone might frequently be taken as evidence of early renal incompetency, and were inclined to the belief that this test would give positive evidence of chronic kidney disease before the appearance of the classical albumen and casts. While in early nephritis estimations of the blood sugar and uric acid were of value, at the other end of the clinical process they found creatinin accumulations offering prognostic information of great value and grave significance. In health and even in kidney disease of moderate degree, creatinin maintained the remarkably constant level of 1 to 2 mgm. in 100 c.c. of blood, but when uremia was impending, this substance in rapidly increased values above 2 mgm. might be looked upon with great concern. Chase particularly had called attention to the prognostic value of creatinin estimations and to their therapeutic application. Joslin had stated that in 45 per cent. of his diabetics an increase in body fat preceded the onset of the disease, and that in 60 per cent. of the fatal cases death was caused by disturbances of fat metabolism resulting in acidosis.

Report of the Committee on Uniformity in the Wassermann Reaction.—Dr. WILLIAM LITTERER of Nashville and Dr. CHARLES WATTERSTON of Birmingham, Ala., drew the following conclusions: (1) A uniform technique and a uniform antigen in the hands of men trained in laboratory work, will give uniform results if

adhered to closely in every detail. (2) Before the results obtained with the Wassermann test are uniform, a method of standardizing the antigen must be found and the men performing the test must agree as to technique.

Syphilis of the Heart and Aorta.—Dr. BRYCE W. FONTAINE of Memphis, Tenn., stated that the records of the Memphis General Hospital for the years 1916 and 1917 inclusive showed a total admission of 219 cases of cardiovascular disease, among which were 43 whites, 176 negroes, 183 males and 36 females, between the ages of 4 and 77 years. Among these patients disease of the cardiac valves headed the list with the occurrence of mitral insufficiency in 133 of the cases, and aortic insufficiency in 24. Next in point of number were aneurysms of the aorta and the peripheral arteries of which there were 18. Such a study showed in the cases of mitral disease 37 or 27.8 per cent. infected with syphilis; in the cases of aortic disease 11 or 45.8 per cent.; and in the cases of aneurysm 11 or 61.1 per cent. From this could be seen how very prominent and common a factor syphilis was in the production of diseases of this character. This fact was suspected more than 50 years ago, and Wagner recorded a very accurate macroscopic appearance of syphilitic aortitis as early as 1866. This author recognized a process in the aorta resembling in some respects atheromatous changes, but in many ways it was unlike atheroma. His experience accorded very closely with that of others, particularly Pearce, in that perhaps 55 per cent. of his cases of aortic insufficiency in adults under 35 showed a positive Wassermann reaction, and an absence of all other etiological factors except syphilis, in the production of the disease. In every case of aortic insufficiency in a young adult, in addition to the physical and other examinations, there should be made a radiographic examination of the chest, for this might be the only means of differentiation from chronic aortitis or aneurysm.

Syphilis of the Stomach and Intestines.—Dr. SIDNEY K. SIMON of New Orleans stated that syphilitic ulcers of the stomach probably represented a breaking down of the gummatous deposits in the mucosa and submucosa. Some of the authorities believed that the obliterating endarteritis, found, as a rule, in luetic granuloma, played an important role in the causation of ulcers. The ulcers had the appearance of a ragged crater on a hardened, infiltrated base, and, unlike the peptic ulcers, were multiple in their distribution over the gastric surface. Again, in contrast to the peptic ulcers, bleeding was a rare phenomenon in the syphilitic type. Syphilitic involvement of the upper intestinal tract was undoubtedly rare. However, instances of such involvement had been described in the literature. Gutman recorded a case in a woman, age 40, presenting a clinical picture somewhat resembling typhoid, with diarrhea, fever, emaciation, etc. On autopsy, the small bowel from the jejunum down showed numerous annular constrictions, corresponding to deep ulcerations on the mucosa. An obliterating endarteritis was present, but no tubercles or giant cells could be detected. Howers had met with an instance of intestinal syphilis in a man, aged 23, who gave a distinct luetic history. Clinically, he complained of a persistent diarrhea with bloody stools and abdominal pain and distention aggravated at night. The patient subsequently died of an influenzal pneumonia, and at autopsy circular constrictions were found in the bowel as a result of cicatrized ulcerations. In the case of the lower bowel, and particularly of the rectum, there could be no doubt of the occurrence of definite syphilitic lesions. It had been his experience that syphilitic ulceration of the rectum was by no means an infrequent manifestation of the disease. Dysenteric symptoms were present, sometimes in an acute form, and a striking analogy was suggested in such well-known conditions as amebic or bacilliary dysentery, or even to malignant disease of the rectum.

Diagnosis and Treatment of Oral Infections. — Dr. THOMAS P. HINMAN of Atlanta, Georgia, said that ever since the relation of oral infection to systemic disease was discovered, an effort had been made on the part of the profession to eradicate the foci that occurred on fully functionating teeth without destroying the masticating power of the individual by extracting the offending organs, and in some instances these curative means had been successful. However, where there had been a great rarefaction of the cancellous structures supporting the teeth, and large foci were present, and the patient suffering with a severe disease traceable to these foci, then extraction and curettage were imperative. Where there were a number of foci in the mouth, it was almost impossible to determine which one was the source of the trouble; therefore, it was imperative that all should be eliminated. Where the teeth were infected, the tonsils were very frequently involved, and in examining the mouth, the tonsils should always be included. A simple examination could be made by depressing the tongue with a dental mirror placed well back at its base and pressed against the tonsil at its lower border; then, by drawing the mirror upward, in this manner milking the tonsil, any infection would become apparent, as pus would show on the surface of the mirror. While this was rather a crude method, it was effective. There were three means of eradicating apical dental foci, and these were: (1) Extraction of teeth and curettage; (2) excision of the root end and curettage, and (3) electromedication through the canal.

Oral Sepsis and the Anemias.—Dr. M. L. GRAVES of Galveston said that anemia constituted but one of the numerous clinical manifestations of sepsis or infection, whether it originated in the mouth or elsewhere. It was a fairly constant symptom in all the grave infections and to a more moderate extent in the less severe ones. Sufficient was known at present to entitle us to more than a suspicion that William Hunter was correct in believing that pernicious or infective anemia should be laid at the door of mouth infection. His own experience tended to confirm this belief, particularly in two recent cases of pernicious anemia. Rigid examination failed to reveal any focus of infection in one patient save the mouth, which showed a bad glossitis and pyorrheal abscesses about all the few remaining teeth. After the administration of 5200 c.c. of blood by citrate transfusion, at intervals, the use of salvarsan intravenously, the administration of HCl and good food and rest, only very temporary improvement resulted, until all of the infected teeth were removed, when the patient made such rapid and marked improvement that he had now resumed a laborious occupation with the appearance of health and a blood exhibit approximating the normal. Cases of secondary anemia, associated with arthritic disease, had responded but poorly to blood tonics, such as iron; but some of them, and one in particular, in a recent experience had responded rapidly to an autogenous vaccine made from the removed tonsils containing abscesses, and the symptoms had improved in a notable way, while resistant to all other treatments, including antistreptococcic serums and stock vaccines. These experiences had led him to the belief that mouth infections were frequently the cause of acute and chronic illnesses, with or without anemia, and to the insistence that every focus of infection be removed in the effort to restore health.

Oral Sepsis and Arthritis.—Dr. J. HEYWARD GIBBES of Columbia, S. C., said that a proper investigation of the gingivæ, teeth, and alveolar processes must include roentgenographic studies. The important relationship of chronic pyogenic infections to a large group of the arthropathies had been conclusively demonstrated, and the first step in the management of these cases should consist in a systematic search for foci of infection. No one portal of entry for infecting microorganisms should be allowed to obscure the importance of investigating all possible sources of infection.

Oral Sepsis and the Cardiovascular System. — Dr. ALEXANDER G. BROWN of Richmond, Va., drew the following conclusions: (1) Focal infection of the mouth, chronic alveolar abscess, chronic pericementitis, acute and chronic infection of tonsils and other oral, nasal, and other cavities adjacent, produce serious, grievous, and dangerous diseases of the heart, endocarditis, myocarditis, pericarditis, and pancarditis. (2) Often unrecognized because of its slow, insidious progress, grave maladies of the heart are produced secondary to gross, filthy, offensive, criminal disease of the mouth. (3) Oral focal infection is the cause, occasion, origin of disease of important organs of the body which must be recognized by the medical profession, which must be impressed upon the laity, and which must in the future diminish

and decrease as the profession instructs and the laity heed the instruction that the care of human mouth and accessory cavities from focal infection, or the early eradication of oral infection, when present, is an insurance against the occurrence of many dreadful systemic maladies. (4) Thorough mouth inspection should be made on every new patient coming for treatment or diagnosis. (5) Old patients, with recurrent diseases, whose condition we may feel we know, should receive careful and painstaking buccal, nasal, and aural inspection, searching for any possible storage of septic bacteria. (6) Dentists must be impressed with the necessity of complete and accurate removal of every focus of primary infection, or else secondary metastases cannot be improved or cured. (7) The roentgen ray is necessary for detecting foci in roots of teeth, whether crowned or not, in bone of lower jaw; but the evidence of gum infection, tonsillar infection, salivary gland infection, must be determined by inspection and study by the diagnostician.

The Relation of Oral Sepsis to the Nervous System.—Dr. E. Bates Block of Atlanta said that he had under his care several cases of epilepsy in which pyorrhea alveolaris or apical abscesses existed, and no other cause for epilepsy could be found after carrying out the usual methods of investigation, and in view of the absence of other discoverable causes and the results obtained, he was inclined to think them due to this focal infection. It must be said that other causes such as syphilis, brain diseases, worms, adherent prepuce, intestinal stasis, etc., were far more frequent causes of this disease. He would not like to be understood as claiming that pyorrhea alveolaris was a cause of epilepsy, but he thought the subject was worthy of further thought and study. He had recently had under his care a young woman, who had five boils on the posterior surface of the thigh, followed in four weeks by spinal myelitis involving the corresponding portion of her spinal cord. The question naturally arose why, with so many cases of oral sepsis, there should be so few cases of nervous diseases produced by it if it was indeed the cause of these diseases. If there was free drainage and the pus was freely discharged, it would seem to be a very different proposition from the cases in which blind abscesses existed or where the peridental membrane was destroyed and toxic absorption was great. With an intact peridental membrane there might be no toxic absorption at all. Although focal infections might be the cause of other diseases, the mere removal of the focal infection did not necessarily cure the secondary disease, as the infection might already have extended beyond the point of focal infection, and the best results were obtained by the prophylactic effect of the removal of the focal infection, or in cases where the secondary disease was produced by the toxins from the point of focal infection.

The Relation of Chronic Infection to Thyroid Deficiency.—Dr. Harvey G. Beck of Baltimore stated that during the past three years, since he had made it a matter of routine to examine all patients suffering with chronic ailments in reference to disturbances of the functions of the glands of internal secretion, he had been impressed in the course of his investigation with two important facts: (1) That glandular insufficiency was of common occurrence and frequently overlooked. (2) That chronic infections were almost invariably associated with glandular syndromes. These infections were usually focal in character and seemed to occur with the same relative frequency in insufficiency of the thyroid, pituitary, gonads and adrenal. Rheumatism showed a special tendency to involvement of the thyroid. Vincent had shown the incidence of 50 to 80 per cent. of swelling and tenderness of the gland in the course of acute rheumatic fever. Billings emphasized the frequency with which thyroid intoxication occurred in young women patients with focal infection in the form of alveolar abscesses, tonsillitis, and sinusitis, while Reede had observed thyroid enlargement in 50 cases under 12 years of age, coincident with chronic gingivitis. He also cited a case in which goiter symptoms were relieved after removal of two abscessed teeth, and another case in which goiter, arthritis, and pyorrhea followed tonsillectomy, from which the patient recovered after treating the pyorrhea and extracting an abscessed incisor. Seventy-eight of the 100 cases in his series at the time of examination suffered with chronic infections, mostly focal in character; 94 either showed evidence or gave a history of infection antedating the onset of symptoms. In several instances well marked symptoms of thyroid deficiency developed after protracted acute fevers. Symptoms appeared in two cases following typhoid, one malaria, one puerperal infection, and one repeated attacks of rheumatic fever. Oral sepsis and inflammatory diseases of the gall bladder and appendix played an important rôle in the relation of chronic focal disease and hypothyroidism, comprising 63 per cent. of the 255 infections present in the series. The remaining 37 per cent. formed a miscellaneous group and included among others pelvic infection, pyelitis, arthritis, amebic dysentery, anal fistula, syphilis, tuberculosis, etc. Oral sepsis embracing tonsillitis, root abscesses, pyorrhea, sinusitis, etc., represented 36 per cent. of the total infections and occurred in 56 of the cases. Chronic appendicitis was observed in 32 cases, and cholecystitis and cholelithiasis in 24. In several instances symptoms of both appendicitis and cholecystitis existed in the same individual.

The Wild Rats of the Southern States as Carriers of Spirochæta Icterohæmorrhagica.—Drs. James W. Jobling and A. A. Eggstein of Nashville, Tenn., stated that their work had shown that hemorrhagic icterus was present in their community, and that about 10 per cent. of the wild rats harbored the causative organism. This percentage of carriers among rats was relatively high and justified them in calling attention to the danger attached to work which brought the individual into more or less intimate contact with the habitats of these animals. This warning would certainly apply to soldiers receiving trench training in the South. In this country and in Europe the mortality had not been as high as that observed in Japan. This might be due to the fact that in Japan the organism had become more virulent because of a more rapid passage from man to man, the rat acting as the intermediate host. This was shown to be true when the organism was passed through several generations of guinea pigs, and the same would probably apply when the organism became accustomed to growing in human beings. It was possible that we now saw the evolution of a new epidemic disease.

Fundamentals in Vaccine Therapy. — Dr. Estill D. Holland of Hot Springs, Arkansas, said that where and when to use vaccine was not so definite, but the newer fields in which he had been using it with good results were in some cases of infectious arthritis, arthritis deformans, eczema, and psoriasis. He had had good results in some cases of psoriasis and he now had on hand an old man with an extensive eczema who would not respond to any other treatment than a mixed stock vaccine. This patient had been with him three times before; every time he arrived he was nearly crazy with eczma; he could not wear a coat or a shirt that touched his neck; his arms were raw to the shoulders and his legs to the knees and his eyes nearly shut. He put him on a stock vaccine, the same as used in arthritis, and he was wearing a stiff collar in six weeks and did not have a trace of eczema on him in two months time. He had also had some good results in injecting the sciatic nerve with vaccines in sciatica, but this he did not consider due to an immunizing effect of the vaccine, but to the consequent trauma of the vaccine reaction in and around the nerve. Stock vaccines should be used in all chronic cases where the disease continued, but in a less active state, and that autogenous vaccines were indicated in acute cases where each exacerbation was as active and pronounced as the previous one.

SECTION ON PEDIATRICS.

Chairman, Dr. William Weston of Columbia, South Carolina.

Classification and Treatment of the Acute Diarrheal Diseases in Infancy. — Dr. John L. Morse of Boston, Massachusetts, said that diarrhea from an excess of fat in an artificial food was not at all uncommon. When the disturbance was a mild one the stools were not much changed in color, but contained many small, soft curds and some mucus, and were somewhat more acid in odor and reaction than usual. Sometimes they were grey

and shiny and in other instances, when there was an excess of neutral fat, they were creamy in consistency and color. Sometimes they looked like curdled milk. In other instances they were bright yellow and had an oily appearance. They were seldom green, unless there was also a disturbance in the digestion of sugar. In the worst cases, they were watery, strongly acid, and caused marked irritation of the buttocks. When this happened, the fat was in combination with the alkaline salts, especially sodium. As the result, there was a considerable loss of alkaline salts in the stools. A relative acidosis was thus produced, with an excess of ammonia in the urine. The symptoms of acid intoxication might then develop. A high fever was not uncommon in these severe cases. The prognosis depended upon the severity of the symptoms, but was in general good, unless there was a marked acid intoxication. The treatment consisted in the complete elimination of fat from the food. It was not enough to diminish it; it must be cut out entirely. In most instances it was advisable to give a cathartic in the beginning and to starve for from 12 to 24 hours. In the cases with acid intoxication, bicarbonate of soda should be given in some way and a food containing considerable amounts of sugar, preferably in the form of glucose or maltose. In the less severe cases protein was usually well tolerated and the caloric value of the food, which was much reduced by the withdrawal of the fat, could be made up by increasing the amount of carbohydrates. Fat could usually be cautiously added again in a few days. How rapidly it could be added could only be determined by observation of the symptoms and examination of the stools. Diarrhea was more often due to an excessive protein in human milk than to an excess of either fat or milk sugar. The protein was most likely to be excessive in the early days of lactation and at the time of menstruation. An excess of protein might also be due to excitement, anxiety and nervousness, or to fatigue or lack of exercise. The diarrhea was usually not serious. The baby was ordinarily not very sick, and the temperature was but little, if at all, elevated. The stools were loose or watery, and often contained fat curds as the result of the increased peristalsis and the consequent interference with absorption. The stools were usually brownish-yellow in color, but might be green. They often contained mucus. The odor was not characteristic; the reaction was alkaline or feebly acid. They were not irritating to the skin. The most important element in the treatment of infectious diarrhea was the diet. The character of the diet depended upon the variety of the microorganism which was causing the disease. These microorganisms could be divided, as far as the determination of the diet to be used was concerned, into two groups: 1. The various forms of the dysentery bacillus and the other organisms, except the gas bacillus, which caused the disease. 2. The gas bacillus and allied organisms. The other organisms, although of many different varieties, were grouped with the dysentery bacilli, because as regards their growth and the production of toxic substances from protein and carbohydrate media, they behaved in the same way.

Malaria in Infants.—Dr. Morgan Smith of Little Rock, Arkansas, stated that malarial infection was less frequent in the infant than in the child or adult. This was not due to any natural protection possessed by the suckling, but to the vigilance on the part of the mother to protect her baby from the bites of all insects. Until the runabout age was reached, the infant took its day naps and slept at night under a cheese-cloth canopy or other similar protection. The discovery of a bite on her baby incited the mother to renewed efforts for its protection. Living under the same conditions, the infant was as liable to malarial infection as the other child or adult, and the closer the observation the more convincing became this statement. Malaria, whether occurring in the infant, older child or adult was a serious disease, and demanded the most prompt recognition and treatment. A positive diagnosis could not be made except by blood examination. A negative blood examination did not exclude malaria; not one, but many and frequent specimens of blood, taken at different stages of the disease, should be made. A therapeutic diagnosis should not be made unless it was impossible to make a diagnosis by blood examination. The treatment of malaria in the infant did not differ from that employed in the child or adult.

Some Observations on Rheumatic Fever in Childhood.—Dr. James D. Love of Jacksonville, Fla., stated that the physician recognized rheumatic fever before the symptom-complex was nearly completed and before the rheumatic cachexia was established. The physician who was most apt to make a tardy diagnosis of rheumatic fever was he who regarded joint symptoms as an essential manifestation of the disease. He could not too thoroughly impress the fact that while at one time or another the rheumatic child would likely display evidence of joint involvement, this was by no means necessary, and should be regarded as merely an incident in the course of the malady. Hutchinson aptly remarked that had rheumatic fever been primarily studied in children it would never have been called acute articular rheumatism. In addition to recognizing the protean manifestations of rheumatic fever, we must particularly bear in mind the extreme vulnerability of certain tissues to the action of rheumatic streptococcus. We might thus be able to detect an insidious invasion of this organism before the customary symptoms were displayed and before our patient had sustained irreparable damage. He knew of no more reliable danger signal than the so-called growing pains of childhood; trivial in themselves but suggestive to the trained physician of the gravest possibilities. These growing pains were usually an expression of muscular or fascial rheumatism, and few greater responsibilities devolved upon us than of educating the public as to the significance of such pains. Of more than casual importance was the suggestion of Williams that the growing pains of girlhood were more significant than those of boyhood The explanation was that the less strenuous life of young girls rendered them less prone to pains induced by overexertion and muscle strain. The general management of rheumatic fever must be influenced by our very inability to detect cardiac lesions in their incipiency. A given case of the disease might be progressing in a manner seemingly satisfactory, yet none of us could state positively that structural damage to the heart was not already in insidious process of development. Bearing in mind that an organ at comparative rest was less subject to infection than when fatigued, it was obvious that a prolonged period of rest in bed must be insisted upon for all our children suffering from even slight attacks of rheumatic fever. Certainly in view of the imminent possibility of cardiac involvement, any case of rheumatic fever called for absolute rest for at least two weeks.

Present Attitude Toward Protein and Fat.—Dr. Oliver W. Hill of Knoxville, Tennessee, said that when possible one should gradually increase the bovine protein as the educative process progressed, until a quantity equal to or somewhat greater than that found in human milk had been reached, for the reason that after all our principal problem was to get the child to assimilate a sufficient amount of protein to cause a consistent gain in connective tissue and muscular strength. We must always be guided by the digestive powers of the patients under consideration, and not by what the books said of calories and percentage. Protein had been grossly misunderstood from the standpoint of normal physiology. It was as much influenced by the individual tolerance or susceptibility as was either of the other food elements. We were learning something of the position of this element and were recognizing the fact that after all was said that we knew, and much that we must conjecture, more depended on the management of the case and the manipulation of the food than on the food itself as to how we succeeded, because a given protein, whether cow's milk or human milk, was practically the same under all circumstances as to chemical constitution, digestibility, etc. Most failures of feeding were not due to the food but to the feeder.

The Rôle of Carbohydrates in Infant Feeding.—Dr. O. H. Wilson of Nashville, Tennessee, stated that granting one had the proper appreciation of the dangers and difficulties of fat, the adaptation and dosage of the carbohydrate was the determining factor in finding the proper food. Carbohydrate was the only element we could qualitatively modify. Normal babies could take with equal benefit either of the three forms of sugar.

Lactose seemed possibly to suit very young babies better. Cane sugar suited older babies as well as any form. Malt sugar was indicated when others failed to produce a sufficient gain, or when malassimilation of fat was evident. The adjustment of the carbohydrate to a difficult feeder was an individual proposition, differing with each case. Starch waters were valuable chiefly through their colloidal action. Any attempt to give enough to displace sugar was disastrous. If a baby had the same trouble taking care of sugar that he himself had had trying to assimilate the confusing, contradictory, indigestible literature on the subject, he was sure he would cut it out altogether.

Eczema in Infancy.—Dr. F. P. GENGENBACH of Denver, Colorado, read this paper, of which the following is a summary: Eczema is a dermatitis due to many internal and external causes, some of which are still unknown and are included in the broad term predisposition. The principal internal cause, aside from the so-called predisposition, is a food intoxication or sensitization, usually combined with faulty elimination. The external causes include all forms of irritation whether mechanical, chemical, or bacterial. The treatment consists in the discovery and removal of the cause or the causes and the relief of the symptoms.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE MEDICAL EXAMINING BOARD.

June, 1917.

(*Continued from page* 1014.)

BACTERIOLOGY.

1. In the diagnosis of typhoid fever, in what stage of the disease would you expect the greatest help from blood culture, and from agglutination, respectively, and why?
2. Mention some of the more common pathogenic organisms contaminating milk, and state the method of procedure when such contamination is suspected.
3. What are the principal means of body defense against organisms which find lodgment in the tissues by wounds or otherwise?
4. What organisms most frequently infect the urinary tract, and what are believed to be the most frequent routes of such infection?
5. Why is an autogenous vaccine usually more effective than a stock vaccine?

PATHOLOGY.

1. Give the etiology and morbid anatomy of acute endocarditis.
2. What pathological lesions are suggested by the persistent elevation of blood pressure above normal during pregnancy?
3. Give the pathology of nephrolithiasis.
4. Discuss the pathology of arteriosclerosis.
5. Discuss the changes brought about by pyrexia in the: (1) circulatory, (2) respiratory, (3) urinary systems.

THEORY AND PRACTICE OF MEDICINE.

1. Give etiology, symptoms, and treatment of acute catarrhal pharyngitis.
2. Give etiology, symptoms, and treatment of pyelonephritis (acute).
3. What is meant by "vocal resonance"? Describe the same (as compared with the normal) in the following conditions: (1) Emphysema, (2) incomplete consolidation, (3) complete consolidation, (4) pleurisy with effusion.
4. Name three cardiac murmurs, and state *when* (with reference to heart sounds) each is heard, and *where*, with maximum intensity.
5. Make a diagnosis of empyema (purulent pleurisy).
6. Give in the order of their appearing the several sets of lesions due to acquired syphilis.
7. Define hematoma, hematemesis, bradycardia, alopecia.
8. Name the most common causes of neuritis, and outline treatment for a case of intercostal neuritis.
9. Describe the lesions of pemphigus and acne vulgaris.
10. Describe the circulatory symptoms of arteriosclerosis.

EMBRYOLOGY AND OBSTETRICS.

1. What is (*a*) Menstruation? (*b*) Menopause? (*c*) Vicarious Menstruation?
2. Describe the fetus at the end of the third month.
3. Describe the changes in the fetal circulation at birth; how long does it take to complete this process in a normal case?
4. What is meant by a justominor pelvis?
5. Give your management of a normal case of labor.
6. Give your management of a brow presentation.
7. In what cases of labor should the exaggerated lithotomy position be used and at what stage?
8. Make a diagnosis of, and treat a case of chorea gravidarum.
9. What diseases might be mistaken for puerperal infection?
10. Give causes, symptoms, and treatment of mastitis.

ANSWERS.

BACTERIOLOGY.

1. In *typhoid fever, blood cultures* are possible quite early in the disease, and are most frequently obtained in the first two weeks; the *agglutination test* is available in the third and fourth weeks of the disease, and rarely appears before the second week. The latter test depends upon the presence of antibodies; and it takes some time for these antibodies to be produced.

2. The *more common pathogenic organisms contaminating milk* are: Staphylococcus pyogenes aureus, streptococcus pyogenes, bacillus coli communis, bacillus typhosus, and the bacteria of cholera, tuberculosis and diphtheria.

When contamination is suspected, the milk should be pasteurized by being heated to 60° to 70° C. for thirty minutes; this will kill all or nearly all of the pathogenic bacteria that are likely to be present. The milk should then be consumed within eighteen hours, so that there will not be time for the development of any spore-forming bacteria, which may have survived the pasteurization.

3. The principal means of body defense against microorganisms which find lodgment in the tissues are: The bactericidal properties of some of the secretions, the bactericidal power of the blood serum, the phagocytic action of the leucocytes and other cells, the germicidal action of the lymph nodes, and the elimination of microorganisms through the secretions and excretions.

4. The organisms which most frequently infect the urinary tract are the staphylococcus pyogenes aureus and albus, streptococcus pyogenes, colon bacillus, tubercle bacillus, gonococcus, and typhoid bacillus. They may enter from outside (instruments, urethral infection), from the circulation, and by passage from intestine into bladder.

5. *Autogenous vaccines* are usually more efficacious than *stock vaccines*, because there are many strains of any given type of organism, and also individual differences of the type; so that a *stock vaccine* is less likely to contain the exact strain of bacterium which is producing the disease. Further, the passage of a micro-organism through the body of an individual frequently modifies the biological characters of such organism; such modifications would be absent from the organisms from which the *stock vaccine* is derived.

PATHOLOGY.

1. ACUTE ENDOCARDITIS. *Etiology:* Simple endocarditis is associated with rheumatism or scarlet fever. Malignant endocarditis is also associated with rheumatism, scarlet fever, and also with pneumonia or septic processes. Micrococci are often found. Chronic endocarditis may follow an acute endocarditis, or may be the result of syphilis, old age, high arterial tension, gout.

Morbid Anatomy: In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium; superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegeta-

tions. These vegetations are most marked at a slight distance from the free borders of the valves—*i.e.*, those parts which come into opposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survive, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact.

As regards the side of the heart most affected—*Congenital* endocarditis attacks the right side of the heart (but note that many congenital cardiac lesions are due not to endocarditis, but to developmental faults); simple endocarditis attacks the left only; the *malignant* attacks *both sides*, though the *left* is much more implicated than the right side.

The vegetations are upon that side of the valve opposed to the blood-stream—viz., at the aortic valve the vegetations project into the ventricle, at the mitral valve into the auricle.

As in pericarditis, the myocardium almost always shares in the inflammatory affection.—(From Wheeler and Jack's *Handbook of Medicine.*)

2. Persistent elevation of blood pressure above normal during pregnancy suggests toxemia and possibly eclampsia.

3. *Nephrolithiasis.*—"Renal calculi are formed in the renal tubules, and may find their way into the pelvis, ureter, or bladder. They may lodge and increase in size in the substance of the kidney or calyces. Though usually small in size, a calculus may occupy the whole pelvis, with branches running into the calyces. The commonest stones are formed of uric acid, next being those of oxalate of lime, then urates, phosphates, and cystine. A stone lodged in the parenchyma may give rise to no symptoms. Pyelitis soon follows lodgment in the pelvis, and the ureter may be blocked more or less, so causing hydronephrosis or pyonephrosis. Complete blockage produces suppression. Perinephric suppuration and discharge of the calculus through a fistula in the loin may occur. The calculus may pass into the ureter, causing renal colic. It then either slips back into the pelvis or reaches the bladder, where it may remain as a vesical calculus or be passed *per urethram.*"—(*Aids to Surgery.*)

4. "*Arteriosclerosis* is a chronic degenerative and inflammatory disease of the vascular system, resulting in an overgrowth of the connective tissue of the arteries, followed by calcareous deposits. The changes may extend to the capillaries and veins. As a result of the impairment of the arterial circulation, there occur fibroid degenerations in other organs, resulting in loss of elasticity in the walls of the vessels, increase of arterial tension, narrowing of the caliber of smaller arteries, and impairment of the nutrition of the organs supplied. . . . The atheromatous changes are most frequent in the aorta. Rokitansky gives the relative order in which atheromatous degenerations occur as follows: aorta, splenic, femoral, iliac, coronary arteries of the heart, arteries of the brain, uterine, subclavian, brachial, ulnar, and radial arteries. The internal surface of the affected vessels is irregularly thickened with gelatinous and translucent, dense and fibrous, or calcareous deposits. If the calcification is extensive, the vessel is changed into a hard, stiff tube. Often the surface of the thickening or deposits is destroyed, presenting the so-called 'atheromatous ulcers,' which may be covered with masses of thrombi. The above conditions are the result of inflammatory change in the intima of the affected vessel which appears three or four times as thick as normal, due to the swelling of its elements, the new growth of connective tissue, and the deposit of round cells. Fatty degeneration of the inflammatory products is the common sequence. The result of the changes in the arteries is a loss of elasticity thus hindering the propulsion of the blood current and raising the arterial tension, ultimately leading to hypertrophy of the left ventricle. These changes finally involve the coronary arteries and lead to alterations in the myocardium. The nutrition of various other organs is likewise impaired when the intima of their respective arteries is involved in the degenerative process.—(Hughes' *Practice of Medicine.*)

5. CHANGES BROUGHT ABOUT BY PYREXIA. (1) *In circulatory system:* Increase in rate of heart beat and pulse; pulse is softer and dicrotic, or full and bounding; the arteries are dilated; blood pressure is lowered; cardiac muscle may degenerate; there is generally a leucocytosis. (2) *In respiratory system:* Respirations are quickened, and the evaporation in the lungs is increased. (3) In *urinary system:* Diminution of the water, chlorides and phosphates of the urine; increase of the urea, uric acid, creatinin and potassium salts of the urine; sometimes the urine contains albumin; and the kidneys may undergo cloudy swelling.

THEORY AND PRACTICE OF MEDICINE.

1. *Acute catarrhal pharyngitis* is due to "exposure to cold and wet, infective microorganisms, local irritants, such as hot liquids and noxious gases, rheumatism, gout, and the eruptive fevers.

Symptoms.—The onset is sudden, usually with rigors followed by fever, thirst, headache, anorexia, coated tongue, foul breath, dryness of the throat, painful deglutition, hoarseness, and a constant desire to clear the throat, due to the increased length of the uvula. Extension to the Eustachian tube and middle ear gives rise to deafness and earache. The nasal tone of the voice is almost pathognomonic. Inspection of the pharynx reveals an intensely red and swollen condition of the mucous membrane. The tonsils and larynx may also be involved. Secretions are first lessened, but soon become increased and assume a thick, tenacious, opaque character. *Treatment:* Twenty-four hours' rest in bed is by far the best medicine for an ordinary cold. Cases resulting from exposure are benefited by the application of bicarbonate of sodium by insufflation. Opium alone or combined with ipecac or camphor will often abort an attack. Pain may be relieved by the administration of salol, gr. iij, phenacetin, gr. iij, and powdered camphor, gr. j, four to six times daily. Tincture of the chloride of iron in doses of 2 to 10 minims may be given. Sodium salicylate, gr. x to xv every hour, for six hours, is of great benefit. Tincture of aconite or potassium citrate may be given to control the fever. The bowels should always be freely opened early in the treatment. Locally the application of a 4 per cent. solution of cocaine or cocaine lozenges will afford considerable relief. Ice pellets in the mouth and heat or cold applied externally also produce benefit. Gargles or sprays of alum (gr. viij to f ℥j), ammonium chloride (gr. xx to f ℥j), or potassium chlorate (gr. x to f ℥j), often relieve the swelling and congestion. The severe cases are nearly always secondary affections, and their treatment is that of the primary diseases."—(Hughes' *Practice of Medicine.*)

2. *Pyelonephritis* "is usually due to extension of sepsis from the bladder in cases of stricture, enlarged prostate, and spinal injuries. It may be due to calculus in the kidney or ureter, or stricture of the ureter. Organisms spread upwards along the mucous membrane or lymphatics of the ureter or along strings of mucus, and cause pyelitis. The bacteria further invade the lymphactics around the renal tubules and give rise to abscesses. Acute inflammation causes death from uremia, but if the process is chronic pyonephrosis is the result. In acute cases a rigor follows an operation on the urinary passages, associated with fever and vomiting. The patient gets into a typhoid condition, and dies

in two or three weeks from uremia. In chronic cases the onset is insidious. There is some pain in the loin and an irregular intermittent temperature. The urine is alkaline and contains pus and casts. The case terminates in death from toxemia. *Treatment:* The cause must be attended to and the bladder regularly washed out, while a large quantity of fluids should be drunk. Hot fomentations and cuppings over the loins relieve the pain, and urotropin is the best internal antiseptic."—(*Aids to Surgery.*)

3. *Vocal resonance* is the transmission of the vibrations of the patient's voice to the ears of the physician during auscultation. In *emphysema* it is diminished; in *consolidation* it is increased; in *pleurisy with effusion*, it is diminished.

4. *Three cardiac murmurs*: (1) That of mitral regurgitation, a systolic murmur, heard loudest at the apex. (2) That of mitral stenosis, a presystolic murmur, heard loudest at the apex. (3) That of aortic regurgitation, a diastolic murmur, heard loudest at the left of the sternum on a level with the fourth left costal cartilage.

5. In *empyema* we find limited motion on the affected side, edema and redness in the intercostal spaces, dulness on percussion, absence of breath sounds, diminished fremitus and resonance, chills, sweats, high fever, dyspnea, and expectoration of offensive sputum; exploratory puncture brings pus, and there is a high leucocytosis. In pleurisy with effusion, hemothorax, and bronchiectasis there will be found no pus, and little or no fever, no leucocytosis.

6. *Lesions of acquired syphilis:* In the *first stage* the chancre is the important lesion. The *second stage* is characterized by: Swelling and induration of the neighboring lymph nodes, sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, and alopecia. The *third stage* is marked by: Anemia, gumma formation, periosteal nodes, headaches, endarteritis and various other diseases.

7. *Hematoma* is a circumscribed collection of blood beneath the skin; it appears as a soft, fluctuating swelling.

Hematemesis is the vomiting of blood.

Bradycardia is a slowing of the heart's action.

Alopecia is baldness, partial or complete.

8. The *most common causes of neuritis* are: Wounds, injuries, compression of nerves, exposure to cold or wet, gout, rheumatism, syphilis, extension of inflammation, lead poisoning. *Treatment of intercostal neuritis:* Rest to the affected side; blistering along the course of the affected nerve; potassium iodide or sodium salicylate may be administered; morphine, hypodermically, may be needed in severe cases; quinine sulphate is often of value.

9. *Pemphigus.* "The affection is considered to be a trophoneurosis. The blebs are situated in the epidermis and probably arise from a sudden effusion from the vessels of the corium as the result of dilatation. The contents of the blebs or bullæ are yellowish or colorless serum, of a neutral or alkaline reaction; the older the fluid, the more alkaline it becomes. In the late stages of a bleb the fluid becomes puriform. In rare instances blood is contained in the bleb. The papillary vessels are dilated and the papillæ, corium, and subcutaneous tissue are edematous and infiltrated with leucocytes."

Acne vulgaris. "An inflammation of the sebaceous gland structure and surrounding tissues. There first occurs retention of the sebaceous secretion, which is soon followed by hyperemia and exudation about the glands and in the gland-wall, and infiltration of the connective tissue, followed by suppuration. If the inflammatory action be severe, destruction of the gland with a resulting cicatrix occurs."—(Hughes' *Practice of Medicine*).

10. *Circulatory symptoms of arteriosclerosis.* "In the early stages, there is lessened elasticity and contractility of the vessels and consequent imperfect and irregular distribution of blood. The heart passes through all the stages from efficient hypertrophy to final dilatation and decompensation. Mor or less dyspnea and palpitation of the heart are usually present on exertion; epistaxis and other hemorrhages are not uncommon; later edema and other signs of cardiac failure supervene. In general appearance the patient may be ruddy, full-blooded, or he may be pale and anemic looking—which is due to imperfect distribution of the blood, and not to poor blood, at least in the beginning. In the early stages major diagnostic importance attaches to visible and palpable evidence of thickening and tortuosity of the superficial arteries, to increased blood pressure (160 to 180 mm. of Hg. or more), to the physical signs of hypertrophy of the left ventricle, a dull, prolonged, somewhat muffled first sound at the apex of the heart (augmented muscular element), an accentuated aortic second sound, and a sloping ascent, broad apex, and slow decline of the pulse wave, especially apparent in tracings. Ultimately the common signs of dilatation ensue; indeed, these may be the symptoms presented by the patient when he first comes under observation. Involvement of the coronary arteries may lead to angina pectoris, the fibroid heart, aneurysm of the heart, thrombosis with sudden death, etc."—(Kelly's *Practice of Medicine.*)

EMBRYOLOGY AND OBSTETRICS.

1. *Menstruation* is a periodic disturbance in the female characterized by a bloody mucous discharge from the uterine cavity; it lasts during the period of a woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. It usually appears between the 13th and 15th year, at the period of puberty; it usually ceases at about 45 years of age, but the period is variable. *Menopause* is the period when menstruation ceases; it usually occurs between the fortieth and fiftieth years. *Vicarious menstruation* is the flow of blood from some organ (other than the uterus) recurring at the monthly periods and taking the place of menstruation. It may occur from the hemorrhoidal vessels, the lungs, the skin, under the nails, the mammary glands, ulcerated surfaces, and many other parts.

2. "At the end of the third month the entire blastodermic vesicle has grown to the size of a goose's egg. The embryonic body is about 3 to 3½ inches long. Sex is perceptible; also eyelids, fingers, toes, and traces of nails. The umbilical vesicle atrophies."—(King's *Obstetrics*).

3. *Changes that occur in the fetal circulation at birth:* The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies. "The ductus venosus and the umbilical vein are obliterated within a week, the ductus arteriosus within a few weeks. The foramen ovale may not close for several weeks or even months; the umbilical arteries are obliterated in their upper portions within five days."—(Polak's *Obstetrics.*)

4. A *justo-minor pelvis* is one in which all the diameters are proportionately shortened; the shape of the pelvis is normal, but the size is diminished.

5. *The patient* should receive a full bath before labor begins and all bed-clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for ten minutes or immersed in mercuric chloride 1:1000 for half an hour. Examinations should be made when necessary to determine the position, presentation, size of the fetus, etc.

During the first stage a rectal enema of soapsuds with turpentine (5i) should be given and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for three doses.

During the second stage, examinations should be made only when necessary. In multiparæ, the membranes may be ruptured with the finger or with some

aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage, 51 of fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for ten to fifteen minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(*Pocket Cyclopedia.*)

6. *Management of brow presentation:* If recognized before the onset of labor, postural treatment may be tried. This consists in placing the woman on that side toward which the fetal face is directed, so as to secure flexion of the fetal head. Failing in this or if only recognized too late for the above to be tried, cephalic or podalic version may be attempted; or forceps may be applied, chiefly to act as a rotator. If the above do not succeed, symphyseotomy may be performed, and the child delivered by forceps. When all other methods fail, if the child is dead craniotomy is indicated.

7. The *exaggerated lithotomy position* may be used in the second stage of labor in cases of contracted pelvis with but slight disproportion between the size of the fetal head and the pelvic outlet. It is also adopted sometimes in cases where version is performed.

8. *Chorea gravidarum.* "When gestation occurs in women already suffering from chorea the disease may rarely be checked. Usually it continues during part or all of the gestation, and may, indeed, last after labor. Frequently the disease is intensified. When mild the movements may be only unilateral; in severe cases they are bilateral and may continue during sleep or induced narcosis. They are often increased as the result of fetal movements or of a physical examination. Chorea may lead to marked deterioration of health, sleeplessness, loss of flesh, paresis, and to various mental disturbances. In severe cases premature expulsion of the ovum may be caused. Recovery from the disease is rare until pregnancy has terminated. The fetus may die *in utero*, or it may reach term and be born weakly or well developed. In some cases it may develop chorea in early childhood. The disease must be chiefly distinguished from hysteria. Some authorities hold that true chorea is rare, and that it is mistaken for hysteria and for maladies des tics. Sometimes chorea and hysteria may occur together. *Treatment.* The general and medical treatment of the disease is the same as in the non-pregnant state. Mild cases may be improved or cured and carried satisfactorily to term. In severe attacks anesthesia may be necessary to control the movements. When the movements are violent, sleeplessness is marked and health deteriorates; the uterus should be artificially emptied."—(Webster's *Obstetrics.*)

9. *The following diseases might be mistaken for puerperal infection:* Typhoid, acute miliary tuberculosis, meningitis, tonsillitis, pneumonia, influenza, appendicitis, tuberculosis peritonitis, acute yellow atrophy of the liver, and cholecystitis.

10. ACUTE MASTITIS. *Etiology:* Infection, generally due to handling; cracked or sore nipples and overactivity of the gland with retained secretion are predisposing causes. *Symptoms:* The breast is swollen, painful, and tender, and, owing to the soreness of the nipple, the breast is not relieved of its secretion, so that it is distended. If suppuration follows, redness, edema, and fluctuation occur over the site of the abscess. The abscess may be—(1) supramammary, the pus lying between the skin and breast; (2) intramammary, or the common form, in which the pus is in the substance of the breast; (3) submammary, which is beneath the breast, and may spread from the deep lobules, but more frequently is due to disease of the underlying ribs. *Treatment,* before suppuration occurs, consists in supporting the breast with a bandage, emptying the gland regularly with a breast-pump, and applying a belladonna plaster over the gland to stop the secretion and allay the pain. When pus is present an incision should be made at once, or the abscess may burrow extensively and riddle the breast. The incision should be made in a line radiating from the nipple, so as not to cut the ducts: it should be free, and all pockets opened up with the finger. Then a large drainage-tube is inserted and shortened daily, as the wound heals by gravitation. If necessary, several incisions are made.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure.

(*To be concluded*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PRACTICE OF MEDICINE. By HUGHES DAYTON, M.D. 325 Pages. Illustrated. Price, $1.50. Published by Lea & Febiger, Philadelphia and New York.

MEDICAL RESEARCH AND HUMAN WELFARE. By Dr. WILLIAM WILLIAMS KEEN. 160 Pages. Price, $1.25. Published by The Riverside Press, Cambridge, Houghton Mifflin Company, Boston and New York.

Miscellany.

A Lady of Accomplishments.—The following advertisement appears in the *Correspondenz-Blatt für Schweizer Aerzte* for October 6: A lady of 31 years wishes a position in a physician's office as reception room functionary. If necessary she can do plain or fancy cooking for a single physician. She is qualified to carry out electrolytic, epilation, and phototherapy. Testimonials and photograph will be submitted on request.

Icterohemorrhagic Spirochetosis.—The literature of this subject is becoming very extensive, as shown by the fact that the periscope of the *Annali di Medicina Navale e Coloniale* for March-April, 1917, contains no less than 31 abstracts of articles on this subject from journals published in a variety of languages. From Italian sources we learn that the disease was at first mistaken for picric acid poisoning and pappataci fever. It can be readily set up and studied in the guinea pig, transmission being accomplished by injection of the blood of human patients. There is no reason to doubt that the affection described by Japanese and English writers exists in Italy. There is no known affection which gives the same syndrome. The mode of transmission is still obscure and the urine in the trenches has been accused. The spirochete perishes soon in the cadavers of its victims.

One Italian author regards the disease as much milder than the Japanese form, less complicated, with frequent absence of recurrence. He also sees differences in the spirochetes themselves and hardly believes that the disease is transportable from the Orient to the Occident. In occidental cases hemorrhage is often lacking. Again there is an occasional association of icterus with relapsing fever, which is also a spirillosis. Bianchi states that the diagnosis is readily made by guinea-pig inoculation, so that the microscope and cultivation are not required. He does not find that the virus passes through a Berkefeld filter. Cultures have been obtained from infectious guinea-pig blood. Other writers speak of a silent type of blood infection which can furnish carriers. Meningitis may complicate the disease and the spinal fluid is found to be infectious in such cases.

The diagnosis may be missed at first. In any case with meningeal symptoms even subicterus of the conjunctiva could be very significant. The rat and the marmot may act as reservoirs for the spirochete. It is not yet proved that so-called epidemic jaundice and Weil's disease of older clinicians are the same as the spirochetosis in question, although inoculation of guinea pigs in Weil's disease have given positive results. Sampietro has made an elaborate study of the two affections, and while he finds that Weil's disease is a spirochetosis notes dissimilarities in the clinical pictures. Weil himself asserts that various epidemics of the disease known by his name have not represented the latter affection. The spirochete, recently found by German bacteriologists, is certainly not the cause of Weil's disease. German veterinary surgeons have described a disease occurring in dogs which symptomatically quite closely resembles Weil's disease in man.

Therapeutic Hints.

Acne.—Richard W. Müller advises the following curative measures for relief of this stubborn condition, due treatment being given at the same time for any constitutional condition:

Jalap	āā 0.02 gm.
Scammony	
Squill	
Calomel	
Amygdalin soap	q.s.

M. Sig.: Divide into 12 pills.

For six days one pill is to be taken every morning on an empty stomach, then to be followed by a second pill half an hour later, with breakfast half an hour after the last pill. While taking these pills no salty food can be eaten, and the mouth and teeth must be kept scrupulously clean. For women the medication must not begin until five days after menstruation. On the seventh day 30 to 40 grams of castor oil at night.

The following spraying lotion is applied to the face by means of a steam vaporizer, mornings and evenings: Infusion of chamomile flowers, 10 grams to 1 quart of water. Put 60 grams of this infusion in the vaporizer and add 5 grams of bicarbonate of soda, or sulphoborate of soda, if the acne is not pustular.

If the condition is pustular, one or two dessertspoonfuls of the following mixture should be used instead of the above:

Copper sulphate	10
Zinc sulphate	35
Camphor	5
Saffron powder	2
Sterilized water	1000

After the evening spraying, the following cream is to be applied to the face:

Glycerite of starch	100
Ichthyol	10
Resorcin	1
Sulphur	4
Camphor	2
Tincture of quillaya	2
Carbonate of magnesia	20

Rose water, q.s. to make a thick cream.

Spread upon face and cover with a sterilized gauze.

Next morning the cream is to be removed, rubbing lightly with a piece of fine linen or absorbent cotton, then apply white vaseline, if there are blackheads. The spray is then to be applied; or if the skin is greasy, a mixture of one teaspoonful of bicarbonate of soda to a cup of hot boiled water is applied instead. Five to ten drops of ammonia in the same quantity of water will also answer the same purpose.—*Hygiene of the Face.*

Sedative for Nerves.—In women during the menopause, nervous symptoms are always present and distressing to the patient. Hare suggests this formula for relief of the same:

℞ Ammonii bromidi.....ʒij (8.0)
Potassii bromidi.....ʒiv (16.0)
Spirit. ammon. aromat....fʒvj (24.0)
Aquæ camphoræ...q.s. ad fʒvj (180.0)

M. Sig.—A dessertspoonful (8.0) to a tablespoonful (16.0) every four hours.—*Practical Therapeutics.*

THE KING'S EVIL AND ITS RELATION TO PSYCHOTHERAPY.*

BY M. ALLEN STARR, M.D., LL.D., Sc.D.,

NEW YORK.

PROFESSOR EMERITUS OF NEUROLOGY, COLUMBIA UNIVERSITY.

WHEN a physician looks back over a long period of activity or glances through the old text-books in his library, one of the striking facts which is forced upon him is the great variety of methods of treatment which have met with success for a time and have later fallen into disrepute and been partly abandoned. In the history of every one of these methods there has been first an announcement of its wide applicability and great usefulness; then a period of trial with resulting enthusiasm and general adoption; then a time of doubt and criticism involving much heated controversy, and finally the settling of definite limitations within which it may be of service. It is realized that the first claim of great success was exaggerated, that subsequent emphatic condemnation was unjust, and that the method had a limited field of usefulness under certain conditions; one of the most important of which has been the personal influence of the originator of and of those who urged the method.

As examples we may cite bloodletting, so universally used in the time of our forefathers; the use of electricity in all forms of nervous diseases advocated by Erb from 1885 to 1895; hypnotism; the suspension treatment for spinal cord diseases used and urged by Charcot from 1885 to 1895; the division of eye muscles urged by Stevens and Ranney for everything from headache and epilepsy to dysmenorrhea in 1896; and the use of tuberculin proposed by Koch from 1900 to 1910.

In each one of these there have been positive results of great benefit to patients. In all there have been disastrous failures—and even in carefully selected cases, where the method seemed peculiarly indicated, success has not always been achieved.

The explanation of the varying results seems to me to be found in the personal influence of a strong mind upon a weaker one; the persuasion that a definite result would follow a given method imposed by a firm will upon a receptive patient. Success has been most often attained by a man of strong positive active character who has believed firmly in the efficacy of the method and has forced his personal belief upon others.

I put out of consideration the charlatans, who from Mesmer down, have consciously played on the fears and fancies of the timid; and the quacks who by advertisement and all kinds of chicanery grossly deceive the public. I refer to men of scientific ability and good standing who know that they accomplish results, and yet from modesty ignore or from insufficient insight are unaware of their personal power in dominating and guiding the fortunes of their patients. As a recent illustration I may cite the rest cures of Weir Mitchell, a great success in the cases he himself treated personally, largely due, as I know from many of his patients, to the power he had to inspire admiration and confidence, to direct their thoughts into new channels, to raise their minds from petty cares and annoyances to broader interests, and to instil a higher type of mental occupation, suppressing introspection and inculcating a new view of life, its duties and opportunities. These, rather than the mere gain of weight and strength, were the essential elements of the rest cure, which rarely succeeds in spite of such gains where the personal element is lacking.

I think we may also cite the results of Christian Science—on which men would not spend their money if they did not get some return—as a further example of the personal element in handling many minor ailments successfully. It is also a matter of fact that since Mrs. Eddy's death the sect is rapidly declining in influence.

If any good has ever come out of psychoanalysis and psychotherapy I am confident that it has been due only to the personal influence of the man and not to any good in the method. But as I do not wish to raise a heated controversy, which is inevitable when this method, now in vogue, is criticised, I will turn to a very remarkable proof of the personal element in therapeutics, not often mentioned at the present time, namely, the cure of the King's Evil by the touch of the King.

English authorities[1] affirm that the custom of curing disease by touch originated in A. D. 1050 with Edward the Confessor. The French[2] claim that the practice was common in France five hundred years earlier, being used by Clovis in A. D. 496; Robert the Pius in A.D. 1000, is also known to have touched for the King's Evil. It had, however, a much more ancient origin. Pliny[3] in his natural history asserts that Pyrhus, King of Epirus, who lived B. C. 300, cured diseases of the spleen by the touch of the great toe of his right foot, the patient lying on his back on the ground. Tacitus[4] relates the story of the cure of both deafness and blindness by Vespasian by touch. The early Christian Fathers, following the example of Christ, cured disease by the laying on of hands; and all through the first ten centuries miracles of healing by touch and anointing

*Read before the Practitioners' Society of New York, December 7, 1917.

are recorded by the church chroniclers. That the power, however, was inherent in royalty, that it was a part of the divine right of kings, was not generally acknowledged in England until the days of Edward the Confessor and in France till the time of King Philip I, 1061 to 1108; but from the eleventh century down to the nineteenth century almost every sovereign in Europe exercised this power and thousands of persons were touched by the King.

The method of healing varied somewhat with different kings. Edward the Confessor is said "not only to have touched, but also to have stroked the

1, Angel of Henry VII (gold); 2, Reputed touch-piece of Charles I (bronze); 3, touch-piece of Charles II (gold); 4, touch-piece of James II (gold).

swollen parts with hands wet in water until worms came out from the openings under the softened scab along with bloody matter removing all the noxious plague, after which at an interval of a week the persons went away cured." Edward I (1270), in touching each person, made over him the sign of the cross and then presented him with a coin, which was at first a penny of copper, but later was made of gold and was worn as an amulet.

In the household accounts of the kings of England, from his time down through the reign of King Charles II, there are records of the expenditure of considerable sums of money each year for these coins. Some of these records are as follows: "On Monday, April 4th, 1278; for 73 persons sick of the King's Evil, 6s. 1d.

"On Monday, April 11, for 192 sick men cured of the King's Evil, 16s.

"At Easter for 288 sick persons cured of the King's Evil, 24s. 4d."

The records show that in one month 533 persons were touched by Edward I. In three weeks in 1316 145 were touched by Edward II; and Edward III touched between 400 and 500 persons in each year of his reign. At the same period in France Charles V and VI were accustomed to cure in the same manner and hundreds of persons were touched by them.

Edward IV had a new coin minted for the purpose of a gift to the sufferers; and it is in his time that the coin was first called an angel, because on one side the figure of the Archangel Michael is shown pursuing the dragon, while on the other side is a ship with a mast in the form of a cross and the legend: "Per crucem tua salva nos Chr. Redempt." The value of this coin of gold was 6s. 8d.*

Henry VII introduced an elaborate church ritual into the method of healing, and this was kept in the prayerbook of the Church of England in one form or another down to the time of George I. The ritual covers four pages of the prayerbook. The records show that it was used on all church festivals, when the King touched hundreds of persons as well as on many private occasions.

At the Reformation under Henry VIII the practice of touching fell into disrepute, only 59 persons being touched by him in three years from 1530 to 1532. But it was revived by Queen Mary and was continued by Queen Elizabeth, who in the early years of her reign touched a large number of sufferers. At this time Dr. William Tooker, the chaplain of the Queen, revised the office in the prayerbook and published it in English,[5] and he also wrote a book in which details of the method used by Elizabeth are given. In Queen Elizabeth's reign the first medical treatise on the subject was written by William Clowes, surgeon of St. Bartholomew's Hospital,[6] for the Queen insisted that she would touch only those who had been examined by her physicians and were actually suffering from the King's Evil. It may have been because of this restriction that during the greater part of Queen Elizabeth's reign she would not touch at all; but she resumed the practice during the last three or four years of her reign and then had a new angel coined which bore the inscription "A Dno factum est estud et est mirabi." This coin was valued at 10s.

In 1604 there arose a great controversy between the French and English clergy concerning the cures, the French claiming that the excommunication of the English sovereigns by the Pope had deprived them of the power of healing by touch, while the English pointed triumphantly to the cures by Henry VIII and Elizabeth as proof of the contrary.

It is certain, however, that Henry IV in France, who was Elizabeth's contemporary, was much more successful than she was in curing. At all the great church festivals he healed, with great ceremony, persons coming to Paris from all over Europe to be cured. It is stated that on one occasion he touched 1,500 persons. They knelt in rows and the King's

*One of these coins may be seen in the collection of the New York Numismatic Society.

physician passed behind each row and held the head of the sufferer in his hands while the King drew his hand downward from the forehead to the chin and then across the face, thus making the sign of the cross and saying: "Le Roy te touche et Dieu te guérit." Laurens, the King's physician, wrote a book,[7] in which he states that tumors diminished in size, and that ulcers dried up; and that out of a thousand no less than five hundred were cured in a few days.

James I, who as a Scotch Presbyterian had little faith in Catholic practices or modern miracles, rarely touched for the evil; yet it is on record that during a visit to Lincoln in 1617 he did touch 50 persons in the Cathedral and 53 at the priory of St. Catherine. On the angel which was coined in his reign the words "et est mirabi" were omitted.

In Shakespeare's play of "Macbeth" (Act IV, Scene 3), King Duncan is supposed to represent James I and in the fourth act is described as touching the sick; this being the only reference to the practice in Shakespeare's plays. The passage is as follows:

Malcolm: Comes the King forth, I pray you?
Doctor: Ay, sir: there are a crew of wretched souls
that stay his cure: their malady convinces
The great assay of heart; but at his touch,
Such sanctity hath heaven given his hand,
They presently amend.
Macduff: What's the disease he means?
Malcolm: 'Tis called the evil:
A most miraculous work in this good King;
Which often, since my here-remain in England,
I have seen him do. How he solicits heaven,
Himself best knows; but strangely-visited people
All swollen and ulcerous, pitiful to the eye,
The mere despair of surgery, he cures;
Hanging a golden stamp about their necks,
Put on with holy prayers; and 'tis spoken
To the succeeding royalty he leaves
The healing benediction. With this strange virtue
He hath a heavenly gift of prophecy,
And sundry blessings hang about his throne
That speak him full of grace.

Charles I, like Queen Elizabeth, required the certificate of a medical examination before he would touch a sufferer, and in his reign the practice of healing was usually restricted to the two weeks about Easter and Michaelmas. He is said to have cured cases of blindness which all through these times was ascribed to scrofula. Even when confined in prison Charles cured the daughter of an apothecary, and after his death cures were ascribed to cloths dipped in his blood.

Cromwell made no attempt to touch for the Evil.

While Charles II was in exile in Belgium many Royalists visited him in order to be touched; on one occasion as many as 260; and the ceremony was carried out with the ritual of the prayerbook. The records of the time give many cases in detail. And after the restoration hundreds flocked to the King, 600 being touched during the first year of his reign. After that it became customary for him to touch every Friday, the candidates being examined by the royal surgeons on Thursday. John Browne, surgeon to King Charles and to St. Thomas' Hospital, has left in his book *Charisma* many details of cases and even asserts that two patients came to the King from America, one from Virginia, one from Portsmouth, New Hampshire. He had a register kept which shows that in nineteen years 90,798 persons were touched by the King. That Browne with his shrewd knowledge should believe in the supernatural efficacy of the royal touch is hardly to be credited and is evidenced by this statement in his book: "Thus every unbelieving man may rest satisfied that without he brings faith enough with him, and in him, that His Majesty hath Virtue enough in his Touch to Heal him, his expectation will not be answered: Whereas the Man of Faith who confides in the same, will as readily find the benefit of the same. And although this method does not always answer expectation, yet its effects are wonderful and its cure most frequent." With this point of view it is not strange to find that Browne insists on certain forms of diet and on medical remedies as very necessary to the cure. The latter can hardly have had much effect according to our ideas of therapeutics.

James II continued the practice of touching, but after the Revolution it fell entirely into disrepute. Macauley writes: "William had too much sense to be duped and too much honesty to bear a part in what he knew to be an imposture." Queen Anne, however, is known to have touched 30 persons at Bath on one occasion in 1702, 200 on another occasion in 1712, among others Dr. Samuel Johnson when he was a boy. The coin or angel given him by the Queen can be seen in the British Museum. Dean Swift brought a protégé to be touched by her, and Daniel Turner, her chief surgeon, testifies in his book, "The Art of Surgery," to a cure of scrofulous glands.

In the prayerbook there is an elaborate ritual which was reproduced in four editions after the accession of George I, but no one was touched by him and he refused many applications to heal. The exiled Stuarts, who for many years lived in France as pretenders to the English throne, were, however, staunch Catholics and from time to time touched for the King's Evil, and records show cases of healing by them from 1715 to 1786.

Thus we see that in England, from 1050 to 1786, every king touched for the evil with considerable success. It is incredible that such a custom should have persisted, and that such large numbers of people should have been touched, and that such confidence in the cures should have been felt, if there had not been ample evidence of the success of the kings in curing the evil.

We could easily cite a similar record from the history of the kings of France. That the belief in the cure was equally strong there is shown by all the documents. Incidentally it may be interesting to note that Louis XI (1461) was deprived of the prerogative because of his many evil ways. Dr. Billings[8] tells a story of the King that after he had an attack of apoplexy he sent for St. Francis of Paula, who was very celebrated for his miraculous cures, but who suffered himself from scrofula. The King, who was a terrible miser, made a bargain with the saint, that if St. Francis should cure his paralysis he would touch him for his scrofula. It turned out that neither could benefit the other in any respect. This was taken as confirmation that the King had lost the power on account of his criminal character.

Louis XIV, XV and XVI also practised touching in France, but at the Revolution an investigation of 2,400 patients touched by Louis XVI showed only five cures. When Charles X was crowned in 1824 Dupuytren brought 124 persons to him to be touched. This is the last record of the practice.

What was the condition known as King's Evil? In all the records it is regarded as a state characterized by swelling of the glands of the neck, commonly called in those days scrofula.

We know that swelling of the glands of the neck occurs under different conditions. It may be a result of a general infection as in diphtheria, measles, or scarlatina; or secondary to catarrhal conditions of the nasopharynx, to adenoids and tonsillitis, or to ulcerations in the mouth; or to wounds in the scalp; or even to lice in the scalp. These are acute cases, temporary, which result in spontaneous recovery when the cause is removed. The more common swellings are tuberculous and are chronic in course, with much spontaneous variation, at times being large, at other times subsiding, and not always going on to suppuration and discharge. Even in the last case after discharge of pus a recovery without treatment may ensue. Hodgkin's disease causes the largest and most persistent swellings and here as well as in cases of malignant tumors recovery is unknown. Lastly a luetic enlargement of the glands may be mentioned which may recover spontaneously. These are the conditions formerly included in the term scrofula. It is evident, therefore, that a spontaneous recovery from this symptom is not uncommon, but was erroneously ascribed to the royal touch, just as at the present time many spontaneous recoveries are ascribed to methods which a scientific physician regards with a large degree of scepticism.

Now in the case of cures of the King's Evil, in cures by the miracles of Lourdes and of St. Anne de Beaupré, and in those of the many affections in which success by questionable methods is attained, it is necessary to recognize the element of confidence in a person as an active agent in the cure. How this element can act we do not know; that it does act we cannot deny. But when we remember that even a slight passing emotion is sufficient to change the electrical resistance in the hands to such a degree as to be measurable by a galvanometer, as demonstrated by Jung and Peterson, we cannot deny that strong emotions, such as were inevitable in preparation for seeing the King, the excitement of the crowd, the impression made by a ritual service of some length, the actual thrill caused by contact with royalty, and the sustained expectation secured by possession of the angel or amulet, might easily set up chemical changes in the system of a stimulating and possibly beneficial kind.

The influence of mind on body, of hope and courage and conviction in giving strength and aiding effort is never to be overlooked; and he is a poor practitioner who does not utilize this influence in the treatment of his patients.

FOCAL SEPSIS AS A CAUSE OF DISEASES OF THE RESPIRATORY AND GASTRO-INTESTINAL SYSTEMS.*

By CHARLES C. BROWNING, M.D.,

Los Angeles, Cal.

Professor of Diseases of the Chest—College of Physicians and Surgeons Medical Department, University of Southern California; Chief of the Tuberculosis Department of the University of California Graduate School of Medicine, Los Angeles.

When we consider how universal is mouth infection and the frequency of demonstrable lesions of the tissues of the mouth in persons who are, clinically, in apparent good health, we may be pardoned if we fail to accept without question the results which are claimed of the wonderful cures by treatment of these tissues. The same may be said of other foci.

We may well inquire whether or not on account

Fig. 1.—Dissection of the mandible, showing the intimate relation of the teeth to the cancellous tissue with the opportunity for spread of infection.

of focal infection, teeth are being needlessly sacrificed and tonsils slaughtered; appendices removed and gall-bladders drained unnecessarily; genito-urinary organs operated upon without sufficient cause; portions of the gastrointestinal tract removed or short circuited unjustifiably. We may safely answer: yes.

However, in the light of the accumulated evidence of competent and trustworthy witnesses should we ask if many such cases which might be benefited by judicious surgical interference or other appropriate treatment, are not being neglected, we would also reply in the affirmative. While some have become over-enthusiastic, others have been ultra-conservative. Fads find their place in medicine. Time is required to form a just estimate when there exist apparent contradictions. Our knowledge of focal infections is in a chaotic state.

Infective organisms may remain in the tissues for years without producing appreciable symptoms, either focal or systemic, and later through some exciting cause produce acute disease, or they may pro-

duce chronic focal and systemic manifestations; or produce systemic conditions when the focal manifestations may be obscure.

Gastric ulcer and other infectious conditions of the gastrointestinal tract have been attributed to focal infection from the mouth. The following résumé of a case is illustrative of an obscure condition of gastrointestinal disease in which relief followed removal of infected foci:

FIG. 2.—Lateral view of a lower tooth showing the cancellous tissue. There had been some resorption of the margin of the bone but the remaining bone is apparently in a healthy condition.

a b c

FIG. 3.—Photomicrograph showing from left to right the tooth, the peridental membrane, and the alveolar process with some of the cancellous tissue near the margin of the alveolar process. *a*, Tooth; *b*, peridental membrane; *c*, alveolar process.

Male, aged forty-two years. Declining health for several years. Unable to work since July, 1915. Gave history of having had pain in region of gall-bladder and vomiting of bile. Greatly emaciated. Had been variously diagnosed chronic gastritis, cholecystitis, tabetic crisis, carcinoma and gastric ulcer. Entered Los Angeles County Hospital, July 8, 1915. Wassermann negative. Fluoroscope failed to reveal abnormal conditions of abdominal viscera. Exploratory laparotomy. Gall bladder drained. No improvement. After several months a number of decayed teeth and roots removed. Improvement rapid. Discharged March 3, 1917.

FIG. 5.—Gum-festoons over the necks of the teeth.

Three cases of chronic empyema-tuberculosis patients, each of whom had had rib resections, entered the Los Angeles County Hospital within a few months. Each suffered from pyorrhea. Two of the cases ceased to drain following treatment of mouth

Fig. 6.—Photomicrograph showing section of a healthy gingival tissue with its epithelial fold and papillæ.

conditions. One was apparently uninfluenced. Attention to the mouths of the above cases was given by Dr. Boland in charge of the dental department of the hospital.

I might multiply cases of success and failure which have come under my observation following treatment of focal infection of the mouth and other portions of the body, but I think it unnecessary.

I discussed briefly focal infections in relation to the etiology and treatment of tuberculosis in a paper read before the Southern California Dental Association, published in the *Pacific Dental Gazette*, September, 1916, copies of which have been sent to the members of this society.

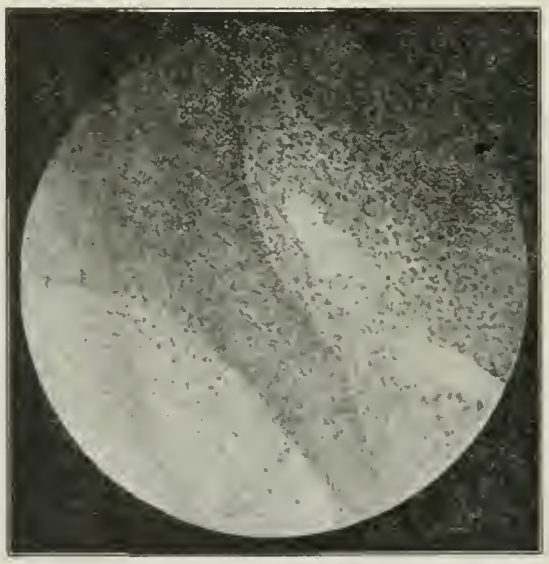

Fig. 7.—Photomicrograph showing papillæ and an early inflammatory process taking place in the tissues of the gingival fold.

During the past few years so much has been written confirming the beneficial results obtained on symptoms and pathological processes in other portions of the body as the result of the elimination of foci, that cases which I might report would be duplicating. Sufficient evidence is at hand; therefore, I think we must accept the influence of focal infections in the production of disease conditions of the thoracic viscera and the gastrointestinal

a b c

Fig. 8.—Inflammatory foci in the pericementum; the fracture of the pericementum is an artifact. *a*, Gingival fold; *b*, pericementum; *c*, cementum.

tract, also the influence of these infections on pathological processes of these viscera.

The finding of a disease focus and its removal does not always prove therapeutically successful, but it does remove one stress to which the individual is being subjected. Other foci may exist and the one removed may not have been the one chiefly concerned in the production of symptoms. All foci should receive treatment in so far as they may be discovered and it is compatible with the best interest of the patient. Disappointments will continue to occur with this as with all other measures of treatment until we are able to appreciate and successfully care for all factors entering into diseased conditions.

We have reached the period in this line of work

Fig. 9.—Chronic inflammation of the peridental membrane, with separation of the latter.

when I believe the improvement of prophylaxis should receive attention, and we should attempt to discover early those conditions, which if neglected will bring about chronically infected foci. For this

reason I am bringing to your attention, to-day, very briefly the condition of one group of tissues which frequently is the seat of focal infection, that of the teeth and adjacent tissues. I desire to consider these from the standpoint of histology and some of

Fig. 10.—One of the extreme later results of infection of the peridental membrane, with which all are familiar. It is an extraosseous infection.

the anatomical relations which favor pathological conditions.

I am indebted to Dr. Julio Endleman, professor of special pathology, etc., in the University of Southern California College of Dentistry, for the use of many of the illustrations herewith presented. They will appear in a forthcoming work by Dr. Endleman on "General and Dental Pathology for Dental Students."

Fig. 4 is a photomicrograph illustrating cross section through the periapical tissue, showing the

Fig. 11.—Resorption of bone resulting from an extraosseous infection.

peridental membrane and the cancellous tissue. It illustrates how readily infection which involves the peridental membrane may spread to the cancellous tissue of the maxillary bone.

Fig. 5 shows the gingiva attached to the alveolar process, falling in festoons over the necks of the teeth, forming a curtain-like extension of the gum tissue folding back on itself, detached from the portion of the teeth which it covers. It is composed of epithelium and a connec-

Fig. 12.—Illustrating early stages of gingivitis.

tive tissue sub-layer. The epithelium consists of a horny layer which externally is resistant, becoming less pronounced as the tissue folds back against the teeth. The connective tissue layer is directly continuous with the periosteum at the margin of the alveolar process and the pericementum. It is composed of closely fitted bundles of fibrous tissue beset with numerous papillæ. It is against the gingiva and the teeth that the salivary calculi are formed which produce irritation and between gingiva and the teeth that serumal calculi frequently produce the lesion for infection. Food may crowd up under this and undergo decomposition, tissues may be wounded, as they frequently are, by the use of the toothpick, etc., starting a focus of infection.

Fig. 8 is a photomicrograph showing to the right a section of a tooth with a fracture of the pericementum which occurred in making the section. The white or clear space shows where the fragment has been separated from the teeth. In the lower

Fig. 13.—Intraosseous infection shown by the *x*-ray, with which all are familiar. In this instance the pathological condition is probably due to a carious tooth having been crowned, the pulp having died and infection extended through the root canal.

part of this separated fragment is seen the attachment of the gingival fold to the pericementum. Its tissue shows inflammatory foci.

Fig. 9 illustrates chronic inflammation of the peridental membrane, showing the separation of

the peridental membrane from the tooth; also the limiting of the inflammatory process. This suggests how extensive lesions may take place without producing discomfort, the process being limited in extent, chronic, and the drainage free. It also illustrates why extreme care should be used in cleaning the teeth in order to reduce the mechanical injury to a minimum, thus preventing the further extension of the disease process. By rough use of instruments the mechanical barriers established for limiting the extension of the infection may not only be broken down, but infectious material may be carried into uninfected areas. Many cases manifest symptoms of sepsis following scaling of the teeth. The area treated should in many cases be limited to a few teeth at one sitting. Even by careful manipulation the lymph spaces are opened and conditions favorable to septic absorption produced. I had one case in whom aching of the joints always followed scaling of even one tooth, which would continue for two or three days accompanied by "hay fever" symptoms. The scaling of three or four teeth would confine her to her bed with slight rise of temperature and more manipulation would be followed by more

FIG. 14.—Showing the limitations of the *x*-ray in the diagnosis of peridental intraosseous inflammation.

intense symptoms. Her teeth were finally extracted. This was followed by gradual but marked relief of symptoms.

Fig. 11 shows the resorption of bone caused by an extraosseous infection. Observe that the root canals are well filled and that no intraosseous infection is revealed by the *x*-ray. Note the overhanging crowns with the marked resorption of the alveolar process. These ill-fitting crowns favor infection. It is almost allowable to paraphrase in expressing the condition of the tooth wearing the shell crown, by stating that infected rests the tooth that wears the crown.

Fig. 12 illustrates a pronounced, moderately early indication in the upper gingiva of the processes which result from the pathological conditions which have been illustrated by the foregoing, while in the lower gingival tissue a more advanced stage is seen. The persistently slightly swollen red line so frequently seen at the margin of the gingiva is the signal of infection at a time when the tissues are amenable to treatment. It is the beginning of a process which usually is painless and does not produce symptoms for many months, and frequently not for years. It is during this early manifestation that the tissue should be treated. I am convinced that few physicians or dentists appreciate this, or recognize the conditions as early as they should. We not infrequently see patients who have pronounced lesions of the gum tissue with recession, who when their attention is called to the condition say that they visit the dentist regularly every six months, or that they have just had a large amount of work completed, and the dentist has neither treated nor called their attention to this condition. Waiting until pus can be expressed from the gums bears the same relation to these conditions that waiting until the finding of tubercle bacilli in the sputum does to the early diagnosis of tuberculosis. Early recognition and early treatment are needed. The *x*-ray is not an aid in diagnosis of early extraosseous infections.

Finally, I wish to call attention to the limitations of the *x*-ray in the diagnosis of peridental intraosseous conditions. Fig. 14 is one of several *x*-rays taken of this patient. No pathological conditions could be recognized by the *x*-ray, yet continued tenderness caused the patient to urge the extraction of the tooth after a year or more of treatment. When the tooth was extracted resorption of the apex of the palatal root was found to have occurred. Marked amelioration of painful affection of the right knee joint which had existed for a year was experienced. Relief has continued since for a period of about six months.

Summary.—Our knowledge of focal infection is still in a chaotic state.

Focal infections are frequent without being accompanied by active clinical manifestations.

Focal infections are productive of systemic manifestations of disease, are the cause of diseased conditions in remote regions of the body and influence unfavorably the progress of other diseased conditions existing in the body. Foci of infection due to the same or different infective organisms may coexist in different tissues of the body.

Care should be exercised in disturbance of extensive foci of infection. Mechanical tissue barriers enter into the protection of the body against injurious influence of infective organisms and their toxins. These also probably act as a protection of the infective organisms against the efforts of the host to rid itself of them.

The virulence of different strains of infective organisms varies, as does also the resisting powers of the hosts. The effect of an infection depends on relative virulence and powers of resistance.

The removal of focus of infection, in such a manner as not to throw too great additional immediate stress on the body, may remove a stress which will have a favorable influence on a diseased condition not due to the focal infection.

The *x*-ray is a valuable adjunct in recognizing these conditions, but cannot be relied on implicitly, either when the findings are apparently positive or negative. It is a link in the chain of evidence. Many cases of chronic focal infection may be prevented if the infection is recognized early. In this paper I have endeavored to call attention especially to a very common one which is easily observed and responds readily to treatment, viz., gingivitis.

600 MERRITT BUILDING.

PRIMITIVE DIETARY LAWS.

By JOSEPH H. MARCUS, M.D.,
ATLANTIC CITY, N. J.
ATTENDING PHYSICIAN TO THE JEWISH SEASIDE HOME.

THE ancient Israelites lived chiefly on vegetable food and fruit upon which the Bible places no restrictions. With the development of the sacrificial system certain restrictions were placed on the use of the portions belonging to the priests, the Levite, and the poor. Besides these, there were also some laws concerning vegetable and tree growths.

1. "Orlah": The fruit of a tree was forbidden during the first three years after its planting. In the fourth year the fruit was brought to Jerusalem and eaten there amid songs of thanksgiving. Those who lived at a distance from Jerusalem might redeem the fruit and bring the money to Jerusalem and spend it in a similar manner. The law of Orlah applied to all times and places.

2. "Hadash": The eating of new corn was forbidden until the second day of Passover, when the "omer" was offered in the temple. This prohibition was also extended to all times and places. The reason for these laws seems to be contained in the sentence, "The first of the first fruits of thy lands thou shalt bring to the house of the Lord thy God."

3. The use for any purpose whatever of the produce of two species of corn or other vegetables sown in a vineyard was forbidden. The sowing of mixed seed in gardens or in fields was also prohibited; but if so sown the produce was forbidden only in case of a vineyard. This prohibition applied originally only to Palestine, but was later extended by the rabbis to all lands and times.

Among the early Hebrews animal food was partaken of only by the common people, only on festive occasions, usually in connection with sacrifices. The permission given to Noah and his children to eat animal food was conditioned upon the abstinence from blood. Some of the learned men were of the opinion that during their journey through the wilderness the Israelites were permitted to eat the meat only of such animals as had previously been sacrificed, some portions of which had been burned on the altar, and some given to the priests; others thought differently. The Bible in its legislative portions makes explicit provisions for the distinction between clean and unclean animals. These are classified as animals ceremonially pure and fit for food, and such as are not.

Biblical Data: The distinction between clean and unclean animals appears first in Genesis vii. 2-3, 8, and where it is said that Noah took into the Ark seven and seven, male and female of all kinds of beast and fowls that are clean; and two and two, male and female of all kinds of beasts that are not clean. Again in Genesis viii. 20, is mentioned that after the flood Noah "took of every clean beast and of every clean fowl and offered burnt offerings upon the altar that he had built to the Lord." It seems that in the mind of this writer the distinction between clean and unclean animals was intended for sacrifices only; for in the following chapter he quotes the Lord, saying: "Everything that moveth shall be food for you." In Leviticus and Deuteronomy, however, the difference between clean and unclean is made the foundation of a food law. The permitted food is called "clean," "pure"; the forbidden food is not simply not clean, but is positively unclean, polluted, impure, and an "abomination." The terminology "clean and unclean" in the food law has to a certain extent a different implication from that born by the same terms as used in the sacrificial laws. The clean animals were:

1. All quadrupeds that chew the cud and also divide the hoof, for instance the ox, the sheep, the goat, the hart, the gazelle, the roebuck, the wild goat, the pygarg, the antelope, and the chamois. Among other animals, the camel, the badger, the hare, and swine were forbidden, and even excluded by name, probably because used as food by the neighboring tribes.

2. Fish proper; *i.e.* "whatsoever hath fins and scales . . . in the seas and in the rivers."

3. Birds. Here the law proceeds by way of elimination. From the rather lengthy list of forbidden birds it may be concluded that all the birds of prey and most of the water fowl were regarded as unclean.

4. The winged creeping things "that go upon all fours" which have legs above their feet to leap withal, of which four kinds of locusts are named. All the other creeping things are most emphatically and repeatedly forbidden and held up as the greatest abomination. A list of creeping things to be avoided includes the weazel, the mouse, four kinds of lizards, and the chameleon. Restrictions were also placed on the use of the flesh of clean animals; it was forbidden to eat it when the animal had been torn in the field by a carnivorous animal, or when it had died a natural death, or had beeen carried off by disease.

For the distinction between clean and unclean animals, many and various origins have been suggested, though few of them seem to have fully satisfied any one but their own originators. The most popular theory at the present time is perhaps that offered by the late W. Robertson Smith in his article "Animal Worship and Animal Tribes among the Ancient Arabs" (*Journal of Philology*); according to which the unclean animals were forbidden because they were the totems of the primitive clans of Israel.

Forbidden as being unclean is also that which comes out of the unclean. This principle applies not only to the young but to all animal products. It is therefore forbidden to use the milk of unclean animals or of animals which suffer from some visible malady which causes them to be legally unfit for food. When after the ritual slaughtering an animal, apparently sound during its life, is found to be diseased, its milk or cheese made of its milk is forbidden as food. An adult may not suckle from the breasts of a woman, although, if placed in a vessel, woman's milk is not forbidden. A child may suckle until the end of its fourth year, if healthy, or until the end of the fifth, if sickly. If, however, it was interrupted after the second year for three consecutive days, with the intention of weaning it, it is not permitted to suckle again.

Eggs of unclean birds, or of birds suffering from a visible sickness, which makes them impure are forbidden. The following signs were laid down by the rabbis, by which eggs of clean birds could be distinguished from those of unclean. If both ends

of the egg are sharp or round, or if the yolk is outside and the white inside, it is of an unclean bird. If one end is sharp, and the other is round, and the white is outside and the yolk inside, reliance may be placed in the testimony of the seller, who must say of what species of bird it comes. As a rule, however, since most eggs sold are those of chickens, ducks, or geese, no questions need be asked. A drop of blood found on the yolk of an egg is considered an indication that the process of hatching has already begun, and the egg is therefore prohibited as food. It is not necessary, however, to examine eggs before using them, to see whether they contain blood. The roe of unclean fishes is also interdicted. Pickled fish may be eaten, though preserved together with unclean fish. The honey of bees is permitted since it is the secretion of the flower gathered by the bee, and then discharged, and contains no portion of the insect. There is, however, a difference of opinion regarding honey produced by other insects.

The ancient Israelite looked with horror upon the custom prevalent among the surrounding nations of cutting off a limb or a piece of flesh from a living animal and then eating it. If the limb was still partly attached to the body, but could never grow again, and the animal was legally slaughtered, this limb had to be thrown away. An animal that has died a natural death, or has been killed in any way other than that prescribed by law, makes impure all persons or things that it touches. One torn by beasts or subject to some mortal disease is regarded as unclean and so unfit for food; "for thou art a holy people to the Lord thy God." Blood, which is supposed to contain the vital element, is repeatedly prohibited in the Bible. It must not be eaten by Jews at any time or place. Not only blood itself, but flesh containing blood is also forbidden. This prohibition applies only to the blood of mammals or of birds, not to the blood of fishes or locusts. Only the blood which is contained in the veins or congealed on the surface of the meat, or which has begun to flow from the meat, is forbidden; as long as it is a part of the meat it may be eaten. The fat of ox, sheep, or goat is forbidden. The punishment decreed for transgression of this law is "karet" (excision) from the community. The fat of birds or of permitted wild animals is not forbidden. The fat of the young found within the womb of the mother after the latter has been legally killed, and its sinew "that shrank" are allowed. The custom of refraining from eating the sinews of the hind legs of an animal arose, according to the biblical narrative, from the incident of Jacob's wrestling with the angel, through which the patriarch became lame. It is not put in the form of a prohibition in the legal portions of the Bible, although the rabbis considered it of Mosaic origin. Birds are excluded from this law.

The threefold repetition of the commandment prohibiting the seething of a kid in its mother's milk is explained by the rabbis as referring to three distinct interdictions: Cooking meat and milk together; eating such mixture; and deriving any benefit from such a mixture. In almost all cases of forbidden food, the transgressor was liable to punishment, only when the portion which he ate was as large as an olive. The ban, however, extends at times further than that; in some cases even to the taste and odor. Hence if a forbidden object falls into a boiling pot of warranted food, all the food contained in the pot is forbidden unless no taste of the forbidden object can be detected in the food of the pot.

It is forbidden to derive any benefit from objects used for idolatrous purposes; meat consecrated to an idol; wine of libation, spices, or anything else used in the idol service is prohibited; in fact any animal slaughtered or wine touched by an idolater was prohibited to the Israelite because it was supposed to be consecrated to his deity; and these prohibitions applied not only to eating or to drinking, but to any benefit derived from it. Even after the practice of idolatry lapsed, these prohibitions remained in force as rabbinical institutions; wherefore the wine of a non-Jew is forbidden. On account of the apprehension of intermarriage, the rabbis also forbade eating the bread of a non-Jew; it is permitted, however, to buy bread of a non-Jewish baker. If part of the cooking was done by an Israelite, the dish may be eaten. Non-Jewish servants may cook for the families which they serve, for since they are in the house of the Jew, it is assumed that one of the household gives occasional assistance. Not only meat, but also milk and cheese bought of a non-Jew are forbidden, because by some carelessness or by a desire to improve, it was feared that the milk may have been mixed with some forbidden ingredient. A Jew is therefore required to be present at the milking, and at the preparation of the cheese. Different customs prevail regarding butter bought of a non-Jew; and in regard to milk and cheese the later authorities are more lenient.

"Sakkanah" or danger to life, is given by the rabbis as a reason for a number of prohibitions included in the dietary laws. An animal that ate poison is forbidden on account of sakkanah. Meat and fish should not be cooked or eaten together; for such a mixture is supposed to cause leprosy. It is therefore the custom to wash the mouth between eating a dish containing fish and one containing meat. Water that was left uncovered over night was not permitted as drink in olden times, because of the apprehension that a serpent may have left its venom in it.

In the laws of "Manu" carnivorous birds—those that feed striking with their beaks, or that scratch with their toes, or live on fish or meat—fishes that eat any kind of flesh, five-toed animals, and strange beasts and birds are forbidden; domestic animals that have teeth in one jaw only, except the camel, are eatable; also the porcupine, the hedgehog, rhinoceros, tortoise, and hare are allowed; the village cock is forbidden, as is the milk of one-hoofed animals. In the laws of "Apastamba" one-hoofed animals, camels, village pigs, and cattle are forbidden; also carnivorous birds that scratch with their feet, or feed thrusting forward their beaks, and the cock. Five-toed animals (with the exception of the bear, porcupine, rhinoceros, and hare), and misshapen and snake-headed fish or such as live on flesh only, are prohibited. One certain sect may eat all animals that chew the cud, with the exception of the camel, and, with the exception of doves, all birds that are not birds of prey. The Egyptian

priests abstained from eating fish, one-hoofed quadrupeds, or such as had more than two divisions in their hoofs and no horns, and all carnivorous birds.

It is certain that the conception of clean and unclean animals did not originate with the Hebrew law-giver, but, in accordance with the Biblical tradition, goes back to prehistoric times, the distinction being assumed as existing in the days of Noah. These unclean (or tabooed?) animals were to be avoided by all persons who laid special claim to holiness, wherefore the priests and saints of all ancient nations were commanded to shun them. Samson's mother, when she was to give birth to a Nazarite was warned against eating anything unclean. The idea that the people of Israel were "a kingdom of priests and a holy nation" could not be more impressively set forth than by the laws which extended to the universal priestly prohibition of unclean food to the entire people. The priest idea is the only possible meaning of Lev. xx. 25, 26: "I have separated you from the peoples, that ye should be mine." The precept given by the angel to Samson's mother shows, however, that the people in general did not heed the dietary laws. The same may be inferred from Ezekiel's words concerning himself as priest: "Ah, Lord God: behold my soul hath not been polluted: for from my youth up even until now have I not eaten of that which dieth of itself, or is torn of beasts; neither came there the flesh of a sacrificially loathsome thing into my mouth." In fact, Ezekiel desires the prohibition of "Nebelah" and "Terefah" (explained below) to be applied to priests only: "The priests shall not eat of anything that dieth of itself, or is torn, whether it be fowl or beast." Thus it is simply an extension of the priestly law to the whole nation, as "holy to the Lord," which underlies the prohibition of nebelah and terefah.

On the other hand, the interdiction of fat and blood rests on different grounds. Maimonides gives a rationalistic explanation, "Blood and fat belong to God, and must be brought upon the altar"; they are divine property; neither Israelite nor non-Israelite is allowed to eat thereof; and the penalty for violation of this law is "karet." Therefore the blood of every animal, even when it is unfit for the altar, must be poured out as water, and the fat of the nebelah and terefah is forbidden. To the same category seems to belong also the ancient prohibition of the sciatic nerve, or rather the gluteal muscle (sinew of the hip) which is upon the hollow of the thigh. This part as representing the locomotive and, therefore, vital power of the animal, could easily be regarded as sacred to the Deity, just as the brain and the heart, and other vital parts of animals were avoided by the Grecks. The prohibition of eating together meat and milk is probably older than the rabbinical interpretation of the law, "Thou shalt not seethe the kid feeding upon its mother's milk, in its mother's milk. Hence in the early schools the question was discussed whether cheese and fowl might be brought together on one table. All these dietary laws, however, intended to give to the Jew the character of priestly sanctity, were declared to be "divine statutes" to which "the evil spirit" and the heathen nations object. The allegorical interpretations followed by the Alexandrians are proof of a prevailing tendency to treat the dietary laws lightly; but the Maccabean reaction against Hellenism lent new importance to them. At the same time, the view is expressed by the rabbis that the forbidden meat shall again be allowed in Israel, as indeed it was believed to have been eaten by the Israelites before entering the Holy Land. The very fact that the whole list of forbidden animals is allegorized in the ancient law books places the dietary laws in a peculiar light, and forcibly recalls their treatment in the patristic literature.

In the Middle Ages the dietary laws became the chief mark of distinction between the Jew and Christian, whose antinomic maxim was: "There is nothing from without the man, that going into him can defile him; but the things that proceed out of the man are those that defile him"; this aphorism in all probability was borrowed from the Gnostic teaching: "We are as little defiled by the meats as the seas by tainted influxes."

Dietary Laws in Islam.—The Mohammedan dietary laws are neither as rigorous nor as numerous as in Judaism. They were not introduced into the religious code until the Medinian period of Mohammed's career. He probably found it unwise to force dietary restrictions on converts, mostly recruited from the poorer classes, who did not despise the meanest foods, and he therefore deferred such legislation to a more propitious time. Certain restrictions, however, were already known, as ancient custom under certain circumstances forbade the eating of camels, but they were ignored by Mohammed. Swine were also probably held in abhorrence. For definite rules concerning diet, Mohammed followed Biblical models; "He has only forbidden you the carrion and swine's flesh and that which has been hallowed to any other deity. But he who is forced by necessity, not wilfully transgressing, commits no sin; behold Allah is forgiving and merciful."

No clean animal is lawful food unless the name of Allah was pronounced while it was slaughtered. Mohammedans are therefore allowed to eat the flesh of animals killed after the Jewish custom. Game is also lawful if killed under the same conditions. Fish and locusts, however, are exempt from this rule as in the Jewish law. The prohibition of wine was introduced gradually. Drinking and gaming, being equally productive of mischief, were discussed together. At first Mohammed was satisfied with simply discouraging drinking and gaming, but later in a revelation he says: "O believers, wine, dice, images, and divining arrows are an abomination of the works of Satan; therefore avoid them that you may prosper." "In those that believe and do good works it is no sin that they tasted wine and game before they were forbidden." All intoxicants were forbidden in this ban, and some theologians even prohibit coffee and tobacco in their teachings.

The term "Terefath," which has been mentioned above several times, signified originally the flesh of a clean animal that had been torn or mortally wounded by beasts of prey, and had been rendered thereby unfit for food. In rabbinical literature the word came to be applied to the flesh of an animal that had received a fatal injury, or suffered any one of certain diseases, or was marked by some physical abnormality, but which otherwise would be "kasher" (fit and proper as food). "Terefah" in

a broader sense includes also a regularly but unskilfully killed animal, in contradistinction to nebelah, which refers to the carcass of a clean animal that has died an unnatural death or been killed irregularly. Both flesh that is *nebelah* and flesh that is *terefah* are forbidden as food by the Mosaic law. The rule is that when an animal is so injured that it cannot live, its flesh is terefah; hence only such injury, disease or abnormality is involved as must cause an untimely death and affect the health of the animal at the time it is slaughtered. The Mosaic law recognizes eight principal terefah signs, as follows: (1) derusah, violent attack by beast or bird of prey; (2) nekubah, perforation of a vital organ; (3) hasurah, natural deficiency of an organ; (4) netulah, loss of an organ; (5) keru'ah, a rent in the body; (6) nefulah, a fall that might cause internal injuries; (7) pesukah, severance or dislocation of a limb; (8) sheburah, fracture of a rib or other bone. In each of these classes there are a number of cases.

Another division of the ancient law gives a list of eighteen principal ones, as follows: (1) When the gullet is punctured or perforated, the hole penetrating to the interior; (2) When the windpipe is split or torn across its width; (3) When the membrane nearest to the brain is perforated; (4) When the heart is pierced as far as one of its ventricles; (5) When the spine is broken and the spinal cord is severed; (6) When the liver is entirely wanting; (7) When there is a perforation through the two membranes covering the lungs; (8) When the lungs lack any of their lobes; (9) When there is a hole in the maw; (10) When there is a hole in the intestines; (11) When there is a hole in the gall-bladder; (12) When there is a hole in the interior, or lower stomach; (13) When the greater part of the flesh covering the stomach is torn; (14) When there is a perforation of the omasum; (15) When there is a perforation in the greater venter, or upper stomach beyond the place where the two stomachs are joined; (16) When the animal has fallen off a roof; (17) When the majority of the ribs are fractured; (18) When the animal has been seized by a wolf with its forepaws or claws. A small bird is terefah when a sparrow-hawk has struck its talons into it; and a larger bird, as a fowl or goose, when it has been struck by a falcon, eagle, or other large bird of prey. Maimonides enumerates seventy indications of terefah, and says: "Seventy terefah are the limit, and must not be decreased or diminished, even though it should be found by scientific investigation that some of the injuries are not dangerous to the life of the animal, or that some unenumerated conditions are dangerous to its life. Only those indications of terefah may be followed which have been accepted by the rabbis and handed down by tradition." Questions of Jewish law cannot be decided by the evidence of philosophers.

A certain book of tabulated data arranges the symptoms according to the various parts of the animal, describing minutely every injury, disease or abnormality, from the head to the hind legs, internally and externally, whether a perforation, fracture, amputation, or discoloration, which might make the flesh of an animal terefah; stating also when such defects are harmless. The lungs are more liable to injury than any other organ; the number and position of the lobes, the bronchial tubes, the tubercles, and any adhesion to the flesh, must be considered. The lungs are inflated to discover any perforation. When the lungs are shrunk it is a sign of fright, and if the fright has been caused by human agency as when an animal sees a man killing another animal, the flesh is terefah; but if the fright was caused by an act of God, as by thunder or lightning, or if the animal has seen one animal kill another, the flesh is "kasher." A test is made by soaking the lungs in lukewarm water for twenty-four hours. In the first case the shrinkage remains; in the second case the shrinkage disappears. Double organs, such as two livers, in an animal or fowl, render it terefah, as the rule is that "a superfluity is to be treated like a deficiency." When the gall is wanting the flesh is terefah, but when a part of it remains it is kasher. A test is made by cutting the liver across and touching the liver with the tongue. There is no bitter taste when the gall is absent. Two gall-bladders render the animal terefah, but when there is a connecting flow between though they appear double, it is kasher.

Some species of fowl, as doves and pigeons, have no gall-bladders, and are kasher. The signs of terefah are mentioned again as being: the lion's attack is fatal to any animal, the wolf's is not fatal to large cattle, like oxen or calves, but it is fatal to small animals, like the sheep; that of a cat or marten, and a fox is fatal only to kids, lambs and fowl; that of a weazel is fatal only to fowls. The lion and the wolf are the most ferocious animals of their size; the attacks of other beasts of prey are not fatal to animals. The attacks of birds of prey are not fatal to cattle, except in the case of the hawk, which is fatal to kids and lambs when it pierces their bodies with its beak. The attacks of ordinary birds of prey are fatal only to birds of their own size, or smaller; that of the eagle is fatal to all other birds. A fall of ten handbreadths renders the flesh of an animal terefah. A shorter fall, if sudden, without a chance of adjustment on the part of the animal, might be fatal, as internal injuries are possible.

In the books of the Ancients, the serpent was made the subject of quite some importance, aside from the question of being terefah. While the serpent is one of the three creatures which grow stronger with age (the other two being the fish and the swine), the intensity and the deadliness of its poison decreases with advancing age. If the poison of the serpent is left in the wound it causes a burning pain, so that one sentenced to die by fire, may be bitten by a snake instead. The poison spreads through the whole body, and it is therefore dangerous to eat the flesh of an animal which was bitten by a snake; and even to wear sandals made from its hide. If the bite of a snake enters the foot, death may result. The snake alone of all animals harms without gain to itself, and is therefore compared to the slanderer. It is also revengeful, but seldom attacks without giving warning by hissing. The snakes of Palestine were considered particularly dangerous; but it is mentioned as one of the perpetual miracles of Jerusalem that no one there was ever bitten by a snake. The flesh of a snake mixed with other things, was considered the most effective antidote against the poison of a snake as well as other animals. Other cures for snake bites are:

placing the bitten part into the body of a hen which had been opened alive; applying to the wound the embryo taken from the womb of a sound, white she-ass; and putting crushed gnats on the wound. A snake cooked in olive oil was considered a curative for itch. A bad wife is called a snake in the proverb, "No man can live in the same basket with a snake," but the appearance of a snake in a dream is a good omen.

A few words concerning "Shehitah." This means the ritual slaughtering of animals. While the practice that prevailed among the nations of antiquity other than the Hebrews, of cutting off a limb from a living animal and eating it is condemned in several passages of the Bible, no definite mode of slaughter is prescribed. There can be but little doubt, however, that in slaughtering animals the priests followed some uniform mode akin to that which was later adopted by all Israel and which is known as "shehitah." The current opinion was that all the laws of shehitah were given orally to Moses by God. One opinion is to the effect that Moses was commanded concerning the shehitah of mammals only, and not concerning that of birds, the latter, therefore, being merely a rabbinic institution. The young found in an animal which has been duly killed may be eaten without the carrying out of the usual form of shehitah, provided it did not step on the ground, *i.e.* if it is used for food soon after being found in its mother's womb. The butchering of animals is entrusted only to persons versed in the law and skilled in their work. Shehitah may not be performed by the following: a deaf mute, idiot, or minor; one who is intoxicated; an old man whose hands tremble, it being apprehended that he may press the knife against the throat of the animal instead of gently moving forward and backward; a non-Jew, even though not an idolater; a Jew who spitefully transgresses the law of Judaism. Some authorities considered women incompetent to perform shehitah, an opinion that came to be generally accepted. The many details of shehitah were summarized by the rabbis under the following five laws, which were supposed to have been delivered by God to Moses:

1. "Shehitah" (delay). There should be no delay or interruption while the slaughtering is being performed. The knife should be kept in continuous motion, forward and backward, until the organs are cut through. A delay of even one moment makes the animal unfit for food.

2. "Derasah" (pressing). The knife must be gently drawn across the throat, without any undue exertion on the part of the operator. It is therefore forbidden to lay one's finger on the blade while slaughtering, as the least pressure renders the animal unfit for food.

3. "Haladah" (digging). The knife must be drawn over the throat. If it is placed between the windpipe and the gullet, or under the skin, or under a cloth hung over the neck of the animal, so that any part of the knife is not visible while shehitah is being performed, although the slaughtering is otherwise properly executed the animal is unfit for food.

4. "Hagramah" (slipping). The limits within which the knife may be inserted are from the large ring in the windpipe to the top of the upper lobe of the lungs when inflated, and the corresponding length of the pharynx. Butchering by the insertion of the knife in any part above or below these limits is called "hagramah" and renders the animal unfit for food.

5. "Ikkur" (tearing). If either the windpipe or the gullet is torn or removed from its regular position during the slaughtering, the animal becomes unfit for food.

Soon after the shehitah the operator must examine the throat of the animal and ascertain whether the windpipe and the gullet are cut through according to the requirements of the Law. In the case of bords and permitted wild beasts, some of the blood shed in the course of shehitah must be covered with earth or ashes, the following benediction being first pronounced: "Blessed art Thou....who sanctified us with His commandments, and enjoined us to cover blood with earth."

BLADDER TUMORS.*

By J. U. REAVES, M.D.,
MOBILE, ALA.

Vesical growths are almost wholly primary and occur most frequently between the ages of forty and sixty. They are more often seen in men than in women, forming about 3 per cent. of all the diseases of the urinary organs. They are rare in children and when they do exist are usually of the connective-tissue variety, and have their origin either in the mucous or submucous coats of the bladder, generally from the trigone, and are found to be multiple in most cases.

Secondary vesical tumors are uncommon, and when present result from the spread of malignant growths situated primarily in the prostate, urethra, or rectum, in the male, and the uterus in the female. Bladder tumors have been estimated to form from 4 to 8 per cent. of all tumors of the body.

Tumors of the bladder are usually situated around the ureteric orifices, being above and lateral to them. This location has led to the view that some irritant substance in the urine may be the cause of such growths. However, we have little exact knowledge of the origin of vesical neoplasms. Growths of the malignant type are found more often around the vesical neck and on the floor of the bladder or trigone. According to Watson, two-thirds of all bladder neoplasms are situated in the lower one-third of the bladder; for this reason the cystoscopist can make a better examination with a cystourethroscope, being thus able to examine the vesical neck and posterior urethra more thoroughly, for no examination of the bladder is complete which does not include the careful examination of the posterior urethra.

Thomson Walker classifies growths of the bladder into the following groups and subgroups:

*Read before the Mobile County Medical Society, Oct. 20, 1917.

1. Epithelial Growths:
   (1) Benign—
      (*a*) Papilloma, villous tumor.
      (*b*) Adenoma.
      (*c*) Cholesteatoma.
   (2) Malignant—
      (*a*) Papillomatous.
         Malignant villous growths.
         Nodular growths.
      (*b*) Infiltrating.
         Epithelioma.
         Adenocarcinoma.
         Alveolar carcinoma.
2. Connective-Tissue New Growths:
   (1) Simple—
      (*a*) Fibroma.
      (*b*) Myoma.
      (*c*) Angioma.
   (2) Malignant—

Sarcoma	Spindle-celled.
	Round-celled.
	Melanotic.
	Rhabdomyoma.
	Chondrosarcoma.

3. Dermoid Cysts.

In almost all cases the first noticeable token of bladder growths is hematuria, coming on suddenly in the majority of instances as a sharp hemorrhage in the urine, or it may be terminal hematuria with just a small amount of bright red blood appearing at the end of micturition, which may pass off, only to reappear until the whole urine is blood stained. This "symptomless" hematuria in a young or middle aged adult may be either intermittent or constant and is usually the first noticeable symptom of a tumor of the bladder. This hemorrhage may continue for days, weeks, or months in spite of any and all palliative treatment, and may cease at any time as abruptly as it began, but this cessation of the hemorrhage does not signify that the cause of the hematuria has corrected itself, and an early examination by a competent cystoscopist is as imperative for the patient's welfare as the early recognition of cancer of the uterus, because tumors that are clinically benign have a tendency to become malignant as they progress; for when the epithelium breaks through the basement membrane of the papilla and begins to invade its axis or main stalk, it should no longer be considered a papilloma, but a papillary carcinoma.

Bladder tumors may remain localized for a long period of time, and when they spread it is either intravesical, intramural, perivesical, glandular, or metastatic; so the earlier a diagnosis is made and treatment begun the more flowery the outlook for a result that will be pleasing to both patient and doctor alike, and the less likelihood of recurrence if treatment is begun early.

Cystoscopic examination should be made as early after onset of hematuria as possible, as the bleeding point is more easily located while hemorrhage is taking place than when it is dormant, and the cases are rare in which the hemorrhage is of such a degree as to prevent a successful cystoscopic examination. This early examination will help to differentiate between the several pathological conditions which would cause hematuria, for we must realize that blood in the urine may come from above—the kidneys and ureters, or from below—prostate, seminal vesicles, and posterior urethra, and drain into the bladder, there mixing with the vesical contents; or the hemorrhage may come from the vesical wall itself.

In the hands of the expert cystoscopist the most trifling, if any, damage is done, and it must be said that the information gained greatly offsets any slight disadvantage which might follow. In my personal experience of several hundred cystoscopic examinations of pathological bladders, it has been rare that any inconvenience befell the patient, and when it did it was most trivial. With such means at hand it would certainly be foolish to rely upon palpation to say whether this or that portion of the bladder wall is indurated, or to classify the "symptomless" hematuria as coming from an irritated bladder neck.

There has been no greater advance in the understanding of the treatment of vesical neoplasms than that which followed the announcement of Beer in 1910 of his technique of high-frequency cauterization of vesical growths. Previous to this announcement the treatment of such growths was in almost all cases surgical, and few could master the technique of Nitze's endovesical treatment, for the skill necessary in the employment of this method was not easily perfected, so most of the surgery of bladder neoplasms was done by the way of cystostomy.

To-day the treatment is divided into operative and non-operative, the non-operative treatment consisting of fulguration of the tumor, and where employed gives a far better result than the older methods. Beer has reported that his first cases treated have been free from recurrences ever since.

Operative methods on bladder tumors are almost always followed by recurrences. They are never practical unless a large amount of apparently healthy bladder tissue can be removed with the base of the tumor. Extirpation of the bladder with transplantation of the ureters may have to be done in some cases. This is a radical operation and is generally followed by ascending infection of the ureters producing infection of the kidney and death.

Operation is indicated only when the tumor is a papillary carcinoma. Fulguration will prove futile in this condition, and its employment will only serve to delay until the patient is in such a physical condition that operative measures cannot be undertaken, owing to the extensive infiltration of the carcinomatous growth and glandular metastasis.

In the operation upon vesical growths the cautery knife is recommended by some to be far superior to the ordinary knife or snaring of the tumors, care being taken to cauterize the edges of the cystostomy wound to prevent implantation of cells from the growth in the incision, this implantation causing recurrences in the line of incision.

For my fulguration work I use the D'Arsonval bipolar current in preference to the Oudin monopolar current. Surgeons differ on this point, but Ashcraft in his report claimed that the D'Arsonval current did more for bladder tumors than surgery, and that it was the Oudin current which stimulated malignant growths into greater activity. I also use either the Brown-Buerger operating cystoscope or the Jos. F. McCarthy cystourethroscope, and for

my direct contact to tumor I use the bayonet-pointed insulated electrode of Jos. F. McCarthy.

The following is a brief report of five cases treated with high-frequency cauterization as outlined above:

CASE I.—Male, age 42, steamboat engineer. First seen in Febraury, 1913. Patient complained of intermittent attacks of hematuria for past eighteen months. His nocturnal frequency was 28 times each night. I asked him how he was so accurate in his count and he replied that each time he had to urinate he struck a match to see what time it was, and that he counted the matches next morning. Cystoscopy showed a large pedunculated villous mass. On manipulation of the cystoscope showers of villi fell from the growth and clouded my bladder media. This patient showed marked improvement in urinary symptoms after first treatment. He was fulgurated seven different times at ten day intervals. Then he changed positions and went to sea. Six months later cystoscopy showed a small nodulation at base of former tumor which was fulgurated. Patient at this time was free from all bladder symptoms and slept all night. Two years later cystoscopy showed a normal bladder.

CASE II.—Female, age 40. First seen in August, 1916. Patient complained of intermittent terminal hematuria which had lasted for a period of two years. Cystoscopy showed a small villous papillary tumor at left of left ureteric orifice. Two cauterizations at two-week intervals sufficied to destroy the tumor. Cystoscopy in July, 1917, revealed a normal bladder.

CASE III.—Male, age 53. First consulted me in January, 1917. Patient complained of frequent urination with terminal hematuria for past two months. Cystoscopy showed a sessile tumor at base of trigone which was about three-quarters of an inch in diameter. Section of tumor with rongeur forceps was reported benign papilloma. Five fulgurations at ten-day intervals succeeded in destroying the tumor. Cystoscopy in September, 1917, revealed a normal bladder.

CASE IV.—Male, age 34. Patient complained of being "strictured" and had been treated for this supposed "stricture" for eighteen months. Cystoscopy showed multiple pedunculated papillomata, eighteen in number, the largest two being situated at apex of trigone just within vesical neck, the others being diffused along both lateral walls of the lower quadrant. At first fulguration the largest two were attacked with the electrode within the pedicle which severed them, and I removed them from the bladder with rongeur forceps, the others being fulgurated ten days later. As this patient was transferred to another section of the country I have not been able to make further examinations, but he reports by letter that he is feeling as though nothing is the matter with him.

CASE V.—Male, aged 62. Patient first examined in July, 1917. Gave history of diurnal and nocturnal frequency for a number of years. Painless hematuria came on suddenly three months previous, which lasted ten days, when it abated. Since the hematuria his cystitis has been more acute and at times he has noticed severe bladder tenesmus. Cystoscopy showed two small pedunculated villous papillomata to the right of the right urteric orifice. Two fulgurations sufficed to destroy these tumors.

SUBLINGUAL MEDICATION.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

IT is strange that a very important matter relating to our practice, and especially to meet emergencies, has hitherto been very little used. True, authors have alluded to it, but have been doubtful as to its value and not emphasized its frequent service to the practitioner.

We are, as I believe, very greatly indebted to Poulson for his brief article in the *Practitioner* (Vol. XCVII, p. 389, 1916) directing attention to its worth. A little later, in the same journal, Cooper added corroborative truth to the striking facts reported by Poulson. In an editorial of the MEDICAL RECORD, Dec. 9, 1916, page 1037, reference is made to the foregoing writers, and it is intimated that their statements should command the consideration they deserve from practitioners. In a letter to the *Boston Medical and Surgical Journal*, Sept. 27, 1917, supplementary to a previous editorial in this journal, I spoke of my own experience during the past summer. This experience has encouraged me to persist when opportunity occurs. Already I have had more than one case in which its great and immediate utility has been proven. I am now very anxious to have other practitioners give a wide and thorough trial to it not only in civil but also in military practice and especially at the front after a battle. Here it would be of untold value when there is no time to make use of a hypodermic syringe, as there are many wounded men who require immediate stimulation or ease from great pain and as speedily as possible.

If the hypodermic syringe be used without every precaution being employed, syphilis may be disseminated far and wide to those previously free from it and possibly tetanus, tuberculosis, or some other fateful disease. To be entirely safe the hypodermic syringe must be sterilized, water boiled, or when used, already distilled, and the skin of the patient thoroughly cleansed with alcohol or ether.

All this takes time and implies conditions which are not available on the fighting line. It must also be remembered that on one or more occasions in practice, hypodermic injections should be repeated. How much simpler and more practical it is to order the nurse or patient to make use of a hypodermic tablet under the tongue, rather than to be forced in time of great emergency to call upon the physician to give the relief imperatively required. Here we find the great value of sublingual medication.

A small hypodermic tablet is simply powdered on paper with a penknife and poured behind the front teeth and under the tongue. In a few moments it is completely dissolved and absorbed, and very rapidly the constitutional effects of the drug employed are observed. If there be great pain, it is almost magically relieved.

If there is heart failure, the circulation may be completely restored when hope is nearly lost. The tablet may be employed as I have counseled, and as it has been done by myself, and others, when consciousness was gone and without risk of any kind to the patient. If the patient is conscious, he is told not to swallow for a few moments, or until the unpleasant taste of the drug is almost if not entirely dissipated.

Since it has now been shown (*Therapeutic Gazette*, August, 1917, p. 539) that the gastric juices render relatively inert the most valuable, in my judgment, of all cardiac stimulants; viz., strophanthus, it is especially valuable to have the sublingual method to recur to when the use of this drug is imperatively required to combat imminent death. In cases of poisoning, or any instances where it is essential to empty the stomach immediately, or in the case of an impacted body in the œsophagus, a hypodermic tablet of apomorphine hydrochloride, gr. 1/15, may be placed in powdered form under the tongue with one of strychnine, gr. 1/30, as has been done by Poulson with the happiest immediate results in a case of impending death from poisoning by chloral.

Personally, I should prefer the use of strophanthus to strychnine to prevent possible death by reason of failure of the respiration, or indeed stoppage of the heart. As to the use of hypodermic tablets of apomorphine, they are indeed the only safe and effective vomitive when the patient is unconscious, or unable to swallow, as in a case, sometimes, of poisoning.

They appeal, as we know, directly to the vomiting centre, and not locally, in the stomach; hence they will act "even when deep coma has supervened." In instances where the mouth is very dry and the patient able to do so, it is desirable to have him rinse it before making use of the tablet in powder, or without preliminary crushing. Apomorphine is liable to change rapidly and it is indicated to have fresh tablets and to protect them by absorbent cotton and colored glass from injurious action of the air, light and moisture. I trust I shall soon hear from my colleagues as to the great practical value of the rapid absorption of powerful alkaloids administered according to the sublingual method. Here is a mucous membrane, very thin, full of vessels, never coated with fur as the tongue and stomach so frequently are, and never as the latter often does, containing food more or less digested and not seldom acids and gases of fermentation, which must surely interfere with or completely neutralize for a time medicinal results which must be rapid in order to be effective and beneficial.

Hitherto, medicines when applied to the mouth have almost invariably been used for merely local purposes. In sublingual medication we obtain very rapid absorption and free from all risks or inconveniences attendant upon the use of the hypodermic syringe. Among these we should cite the puncturing of a vein, the injection of air, the irritative effects often produced and resulting in local pain, swelling, or abscess. The introduction of the needle and injection into a vein may even be followed as we know by a suddenly overwhelming effect, or even death, sometimes due to entrance of air into a vein.

42 West Thirty-seventh Street.

Medicolegal Notes.

Employees' Authority to Hire Physicians.—The Iowa Supreme Court holds that an assistant engineer, in charge of certain grades and bridges, with power to hire and discharge men, and hire physicians, in the absence of company physicians, to care for injuries, has no implied authority to hire a physician for a servant injured while not at work. A physician called on by an assistant engineer to care for injuries to a servant of a railroad is required at his peril to ascertain whether or not the servant was injured in the course of his employment. It has been held that authority to employ a physician is not to be inferred from the mere fact that an employee is roadmaster, conductor, foreman, yardmaster, or general surgeon.—Carson v. Chicago, etc., R. Co., Iowa Supreme Court, 164 N. W. 747.

"Personal Injury" and "Disease"—Workmen's Compensation Acts.—The Massachusetts Supreme Judicial Court holds that neurosis of the nerves supplying certain muscles resulting from a posture which causes a cigar maker "to bend with shoulders forward," so as to induce "pressure on the brachial plexus," is not a personal injury arising out of and in the course of his employment within the meaning of the Massachusetts Workmen's Compensation Act. A disease of mind or body which arises in the course of employment, with nothing more, is not within the act. It must come from or be an injury, although that injury need not be a single definite act, but may extend over a continuous period of time. Poisoning, blindness, pneumonia, or the giving way of heart muscle, all induced by the necessary exposure or exertion of the employment, fall within well recognized classes of personal injuries. On the other hand, the gradual breaking down or degeneration of tissues caused by long and laborious labor is not the result of a personal injury within the meaning of the act. A person may exhaust his physical or mental energies by exacting toil and become unfit for further service, but he is not because of this entitled to compensation, for the reason that his condition cannot fairly be described as a personal injury. The disease must be, or be traceable directly to, a personal injury peculiar to the employment. A nervous condition dependent upon poor posture of the body does not constitute a commonly known and well recognized personal injury consequent upon employment. It is difficult to establish and define a plain line of division between what is personal injury within the act on the one hand and simple disease on the other hand. But personal injury and disease are not synonymous. They are different in meaning. One does not include the other. They are classifications differing from each other in kind, although they may overlap in some instances. —In re Maggelet, (Mass.) 116 N. E. 972. Under the Michigan Workmen's Compensation Act, providing for compensation for accident and injury to or death of employees, no compensation can be recovered except for accidental injuries, therefore a workman who ruptured himself while lifting an iron bar in his usual manner is held not entitled to compensation.—Kutschmar v. Briggs Mfg. Co., Michigan Supreme Court, 163 N. W. 933.

Receiving Patients into Home—"Dwelling."—A covenant in a deed to use the property as a dwelling will not be violated where a physician so occupying the premises receives a few patients into his home for treatment.—Booth v. Knipe, New York Appellate Division, 165 N. Y. Supp. 577. In Gallon v. Hussar, 172 App. Div. 395, 158 N. Y. Supp. 895, the Second Department of the Appellate Division held that a similar covenant should not be so construed as to prevent a physician from taking a few patients into his own home for treatment or from taking boarders; and in Smith v. Graham, 161 App. Div. 803, 147 N. Y. Supp. 773, in an opinion adopted by the Court of Appeals, 217 N. Y. 655, 112 N. E. 1076, it was held by the Fourth Department that a covenant which it was expressly agreed should run with the land, to erect only a dwelling, but reserving to the grantee the right to receive and care for medical and surgical patients, was no broader with respect to the reserved right to care for medical and surgical patients therein than would have existed without it.

Military Medicine.

GAS GANGRENE.

THE frequency with which war wounds are complicated with gas gangrene, caused by the *Bacillus welchii*, has stimulated much research in an effort to locate the causative conditions in order to facilitate prevention and treatment. The frequency of gas gangrene in the battlefield is due rather to the peculiar nature of war wounds than to a specially polluted soil, although it is true that the soil may be polluted by the spores coming from the intestinal tracts of sheep or other domestic animals. In civil life, wounds are usually wide and gaping, making for aerobic conditions inimical to the development of the anaerobic gas bacillus. But war wounds are usually intricate and narrow channeled, the channels sealed or choked with bits of clothing, blood clots, and tissue; excellent anaerobic conditions are thus produced. The microorganism enters as a spore, and never as a bacillus. It remains for the favorable conditions established in the wound to allow the spore to vegetate. It seems that wounds that are superficial, that do not penetrate beyond the connective tissue are little likely to develop gas gangrene because the superficiality allows the ingress of air, producing aerobic conditions. It is the deep muscular wound that is commonly the seat of infection, partly because the depth of such a wound effectively excludes air, but as much for another condition connected with the medium necessary for the development and growth of this bacillus.

In wounds involving the superficial connective tissues the exudation—lymph, serum, and blood cells, is rich in protein but poor in carbohydrates. *Bacillus welchii* will not grow in a pure protein medium. Muscular tissue, however, is rich in glycogen, and is the medium par excellence for the growth of this bacillus. A medium rich in fermentable carbohydrates is the ideal, since ordinarily fermentable carbohydrates encourage the growth of most bacteria while the sugars in solution and in concentrated form prevent or inhibit their growth. This latter fact has been responsible for the large use of concentrated solutions of sugar in the treatment of war wounds, but from the viewpoint of these researches it would seem that the application of sugar solution to wounds infected with the gas bacillus would be disastrous. *Bacillus welchii* probably does not produce a soluble toxin. In the presence of fermentable sugars it produces butyric or other organic acids that are highly irritating or otherwise injurious to the tissues. Moreover, there is a mechanical action of pressure, caused by the stormy and often explosive reaction in the process of fermentation, which injures the tissues. In some examinations of soldiers' uniforms 100 per cent. were found infected with *Bacillus welchii*, and nearly 75 per cent. of all wounds examined harbored the bacillus. When the wide treatment of war wounds with sugar is allied with the other conditions necessary for the growth and development of this bacillus the large number of cases of gas gangrene is explained. On the other hand, it has been shown that while weak saccharose solutions encouraged the development of these cases a concentrated solution prevented them. The bacilli can develop in the presence of saccharose up to 40 per cent., but not beyond 60 per cent. The introduction of oxygen experimentally merely reduced the amount of gas evolved, but had no effect on the bacilli, as would be expected from the fact that this bacillus is anaerobic.

The fact that a soluble toxin is probably not produced by the gas bacillus was believed to be the obstacle in the way of the production of antitoxin. Yet Bull and Pritchett of the Rockefeller Institute have developed an antitoxin which although not tried out in the trenches has proven successful in animal experimentation. It is to be hoped that by this discovery they have overcome the difficulty in the way of the antitoxin treatment and removed one of the prolific causes of war mortality.

Sepsis in Gunshot Wounds of the Kidney.—Col. Andrew Fullerton, writing in the *British Journal of Surgery* for October, 1917, says that sepsis is present in most war wounds, and is especially likely to occur in kidney wounds for the following reasons: (1) A large amount of blood is thrown out into the loose perirenal connective tissue. Both blood-clot and loose connective tissue are notoriously favorable to the development of infection, once microorganisms are introduced. (2) Owing to the absence of collateral circulation in the kidney, a certain amount of gland tissue in the immediate vicinity of the wound dies. The dead tissue forms a suitable medium for the growth of microorganisms. (3) If the adjoining colon is bruised or damaged, the entrance of intestinal microorganisms on feces transforms the wound at once into a septic one.

Anesthetics in War Hospitals.—At a meeting of the section on anesthetics held by the British Royal Society of Medicine on November 2, 1917, the question of anesthetics in the British Home Military Hospitals was discussed. Lieut.-Colonel J. P. W. Silk, S. A. M. C., opened the discussion. In the course of his remarks he said that the use of pure undiluted chloroform was contraindicated. He thought, however, it was of value in many cases, especially when given diluted with ether and by the open method. For short cases three methods of anesthesia were useful: (1) Local anesthetics, perhaps not used as often as might have been expected before the war; (2) Nitrous oxide; (3) Ether, which should be given preferably by the open method. Silk was of the opinion that a preliminary injection of morphine and atropine should be almost a routine. If ether was to be administered atropine should always be given as it dries up the mucous membrane. He would inject it half or a quarter of an hour before the operation, and it should be given in the operating room rather than not at all. When time was no object he thought ether should be used from the beginning, otherwise it was best to begin with a mixture of chloroform and ether.

Less chloroform and more ether had been given in British home hospitals in the past year with increased safety to the patients. Silk thought that in shock too much morphine could not be given, but it should be avoided in septic cases and in patients with malaria or heart trouble. In such cases chloroform should be avoided also. As little anesthetic as possible should be given,

and it should be diluted with oxygen, which could be bubbled through the ether. Nitrous oxide and oxygen were valuable, but the apparatus militated against its use and he was not satisfied as to the anesthesia which was produced. Warm ether was of advantage in these cases. In intracranial cases morphine was unnecessary, and here also very little anesthetic should be given. He preferred chloroform as it lowered venous congestion. In empyema he preferred intratracheal methods and as anesthetics he used chloroform and oxygen. In spinal cases in which, owing to the position of the patient, venous congestion was always present, he thought chloroform and oxygen the most desirable anesthetics. In orthopedic surgery spinal anesthesia was not used to the extent which might have been imagined.

In plastic surgery of the face and allied conditions the chief difficulties were caused by the blood and mucus which collected in the mouth and pharynx; there was also difficulty of manipulating the anesthetic with a fixed or very mobile jaw. In the majority of cases exceptional methods were necessary, and of these he mentioned four: (1) Intratracheal. This was not necessary in all or even in the majority. (2) Intubation was little known in England, but had many advantages; it was easy to introduce Kuhn's tube, which could be packed with gauze round the pharynx, thus preventing blood from entering. (3) Rectal ether-oil method. In this there were two important points: (a) the patient should have morphine and atropine before, and (b) the anesthetist should himself see that all remnants of ether-oil were washed out of the rectum. (4) The sitting position. In this the patient sat bolt upright and anesthesia was produced by passing oxygen and chloroform or ether vapor through a nasal tube. This method had been in use, Silk said, for over a year at one of the principal facial hospitals and so far no fatality had occurred.

Treatment of Wounds By a Solution of Soap in the Casualty Clearing Station.—R. Garside Dixon and H. T. Bates, writing from a casualty clearing station in France, tell how their attention was drawn to the treatment of wounds by soap solution used by French surgeons. Seeing such excellent results, they tried the same method of dressing wounds on 368 cases within a few months. In order to have proper comparison of results, they treated similar wounds at the same time with other antiseptics, including eusol, hydrogen peroxide, and B. I. P. P., with the result of an increased use of the soap solution in preference to the other antiseptics.

Common yellow soap upon analysis was found to contain per cent.: Water, 24.6; fatty acids, 63.0; combined alkali, 4.6; free alkali, nil; impurities, 7.8. This was considered suitable when made into a 2½ per cent. solution.

The first cases to undergo this treatment were those of small open muscle wounds in which no gas gangrene was present. After being opened up and metal and cloth removed, the wounds were dressed with sterile gauze soaked in this solution. The dressings were left undisturbed for two, three, or four days, provided there was no rise in temperature. At the first dressing the most striking features were less pain, the unusually clean appearance of the wound, absence of pus, and the redness of the whole tissues, the muscle in particular. Encouraged, they tried the same treatment in larger and deeper wounds, using Carrel's tubes in the ordinary way. Here a difficulty was encountered with the soap solution, as it was found to be too gelatinous to flow at all well down the tubes. However, a 2½ per cent. solution of the B. P. soft green soap was then tried, and gave excellent results.

Next, compound fractures of the bones of the hands and feet, also the long bones, including the femur, responded satisfactorily to this treatment. Cases of penetrating wounds of the knee joint received this method of treatment, the joints being irrigated and the capsule and external wounds closed. These gave excellent response, as did also cases of gas gangrene. In one of the latter cases a gelatinous film or glaze formed over the affected muscles, so the treatment was changed to one in which hydrogen peroxide was employed.

In one case where a man had similar wounds of both calves the soap solution with Carrel's tubes was used on one leg, and another antiseptic, also with Carrel's tubes, was employed in the other calf wound. While both wounds did well, the one treated with the soap solution gave the better result, in spite of the fact that it was not dressed as frequently as the other leg, and the wound looked more like a granulating one and nearer the closing period than the other wound.

The soap solution offers these advantages over the other antiseptics, according to these investigators: It cleans up a wound quickly, the dressings are much less painful than ordinary dressings, and at the same time they do not require changing as often as the other types of dressings, thus saving labor. A wound dressed with this solution needs to be changed but once in every three or four days. Then, too, the solution is easily procured, easily made, and very cheap.

Seventy-three superficial wounds, 160 uncomplicated severe wounds involving muscle, 105 compound fractures, 30 joints, 14 amputations, 17 vessel wounds, and 6 nerve wounds in all were included in this series of treatment, giving both encouraging and satisfactory results.—*The Lancet*, Nov. 24, 1917.

Vincent's Angina Among the Troops in France.—Vincent's angina has always been a dreaded condition and one difficult to handle. Now R. J. C. Bouty, reporting through the *British Medical Journal* for Nov. 24, 1917, tells that this condition has been on the increase for the past two years among the army in France, both French and British. In peace times this disease forms about 2 to 3 per cent. of all cases of throat trouble among the French army, while recent statistics from a British military hospital in France show the proportion to be as high as 23 per cent.

From a study of cases under his own observation, Bouty found that this disease is characterized by the formation of ulcers on the buccal and pharyngeal mucous membrane, either superficial or deep, covered by a pseudomembrane, and the most common site is the tonsil. The disease is caused by an organism normally present in the mouth of healthy

individuals, but seems to favor irritated conditions of the mucous membrane. Vincent himself considers smoking to excess as one of the chief predisposing factors, as also the presence of decaying organic matter, and any irritant fumes, such as those given off from exploding shells. This disease is prevalent among students working in the dissecting rooms, and in hospitals generally, and among nurses.

It presents a sudden onset and may be preceded by a few days' malaise. The temperature is raised for the first day or two, and may be high, the membrane often not beginning to form for twenty-four to forty-eight hours after the commencement of the fever. Then it is rapidly formed, is thick and abundant, and usually appears on one tonsil at first. After the first two days the temperature may fall to normal and remain so, or there may be an irregular slight pyrexia throughout, which occurs more often in the severe type with complications, such as marked adenitis or albuminuria, etc. The membrane is yellowish-white and abundant and adherent, and leaves a raw, bleeding surface on removal. Although the tonsil is the usual part affected, the ulcer may spread from this location to any part of the throat, causing destruction of tissue. The breath has an unpleasant odor, worse than in the diphtheritic throat.

As a rule, if treated thoroughly, the membrane disappears in a few days, but in some severe cases, even after two weeks of apparent recovery, another ulcer may appear on the opposite tonsil, with recurrent temperature. Sometimes a chronic form of this condition is to be found, with serious complications. Some cases of death have occurred in French hospitals in which the primary cause was Vincent's angina.

Microscopically, two varieties of organism are found, the *Bacillus fusiformis* and Vincent's spirochæte. Two forms of Vincent's angina are met with—(1) the pseudo-membranous, resembling diphtheria in appearance, and (2) the ulcerative form. In the first we find abundant bacilli mixed with cocci, and in the second, associated with the bacillus, a Gram-negative mobile flagellated spirillum. A coexisting streptococcal infection is not uncommon, and may give rise to serious complications.

The Ziehl-Nielson method is all that is required, though the silver method demonstrates the spirochaete more clearly. Injected into animals the organisms are non-pathogenic. Injection of impure cultures causes abscesses in which the spirochaete is abundant.

Letulle states that in every case of ulceration in the mouth, whether syphilitic, tuberculous, or cancerous, large numbers of *B. fusiformis* and spirilla are to be found.

The complications of this condition are those to be expected in the tissues of the mouth and throat as well as in those to which the infection has been carried. Adenitis of the cervical glands occurs in nearly every case and is very painful; pyorrhea alveolaris is often present, as also is stomatitis and gingivitis, while quinsy is a frequent complication. Gastroenteritis cases have occurred, in which postmortem, abundant bacilli and spirochetes have been found in the intestines. Nephritis and albuminuria, already mentioned, are to be looked for, and there is very frequently a trace of albumin in the urine of these cases. The tissues of the ear and breathing apparatus come in for their share of complication in many of these cases, and perforation of the carotid artery has been caused by the presence of one of these ulcers on the pharynx. An association of Vincent's microbes complicating a syphilitic chancre of a phagedenic tendency has been noted by Laimos, and the same association has been observed in soft chancre. A case of thrombosis of the left saphenous vein with gangrenous ulceration of the leg, complicating Vincent's angina, has been recorded by Guinsberg. Bouty also reports one of his own cases in which the uvula was the only part attacked, leading to complete destruction of the posterior portion and tip, a very small part only remaining. Some men have reported osteomyelitis as a resulting condition from this same cause.

In an uncomplicated case the symptoms are sore throat, headache, and pain behind the eyes; after the first day or two there may be no symptoms aside from the slight malaise, while in the more severe cases there may be loss of appetite, wasting and great prostration.

In the treatment of this condition the drugs which have proved of benefit are calomel in repeated small doses, but Vincent states that mercurial treatment aggravates the condition when the patient is not a syphilitic. Arsenic and a mixture of sodium salicylate and potassium chlorate have been used, and tonics locally. Mercury perchloride and glycerin (1 in 500), silver nitrate, methylene blue, neo-salvarsan, solution or powder applied daily for three days, and frequent gargles of hot hydrogen peroxide have been recommended.

The treatment which Vincent himself finds most effective is a thorough painting with tincture of iodine 6 per cent., after the membrane has been thoroughly removed.

In some cases a dose of antidiphtherial serum has given much relief. The importance of treating the unaffected side of the throat must be borne in mind to prevent occurrence on that side. Salvarsan intravenously (one dose) has been said to modify this condition and to prevent occurrence.

Vincent's angina is to be diagnosed from diphtheria, all types of tonsillitis, syphilitic ulceration, primary and tertiary, and scarlet fever. In every case a culture should be made to establish the absence of Loeffler's bacillus. The Wassermann reaction in this condition is negative. Certain skin conditions, such as erythemata and bullous eruptions, have been reported, but are probably due to coincident streptococcal infection.

Bouty considers that Vincent's angina is a more serious complaint than is supposed; its general effect on the system is so often severe, probably from the abundant absorption of toxins. Recurrence may take place even three weeks after the first attack, in which case complications are more liable to occur.

Munition Works Ordered to Provide Hospitals.—A conference of the sub-committee on industrial diseases, poisons, and explosives, which is working under the direction of the National Council on Defense, was held at the Hotel McAlpin, in New

York, on December 1. Recommendations were formulated for presentation to the Council on National Defense requiring all munition plants in the United States to establish hospitals under the care of a competent physician and to provide restaurants where the employees may eat without danger of being poisoned by substances used in the manufacture of munitions. It was recommended that the work in the plants should be so regulated that the workers should not come in direct contact with nitro and amino compounds.

Employment of Cripples.—At a meeting of the New York State Industrial Conference, at which industrial leaders from all sections of the State were gathered, on December 3, emphasis was laid on the fact that provision must be made by our industries for the employment of wounded and crippled soldiers returning from the war. In speaking on this subject Carleton A. Chase, president of the Associated Manufacturers and Merchants of New York State, said "This taking care of our war-battered boys is not a welfare work, nor is it sentiment. It is common justice."

Health Conditions at Army Camps.—A statement issued on December 17 by Surgeon General Gorgas, after a tour of inspection of four of the army camps, confirms the reports that have been in circulation that there has been an insufficiency of winter clothing which has been the cause of much suffering among the soldiers during the intensely cold weather. With the exception of the hospital at Camp Funston, none of the base hospitals have been completed. Surgeon General Gorgas has recommended the rushing of this work. He points out that practically all the disease in the camps has been brought there by the incoming men, and recommends the establishment of observation camps for all newcomers, so that they may be kept under observation for such a length of time as the division surgeon shall deem necessary. To aid sanitary conditions he recommends that fifty square feet of floor space shall be furnished at all camps for each man; in some camps only twenty feet is now provided. At Camp Bowie, forty-one deaths from pneumonia are reported out of 400 cases admitted to the hospital. About 2000 cases of measles have developed during the same period. At Camp Funston, during the last month, there have been forty-three deaths from pneumonia, with 189 cases, and twenty-two deaths from meningitis, with seventy cases. The report states that for the week ending December 14 the pneumonia conditions in all divisions of the national army have improved decidedly over the previous week, except at Camp Travis, where there are seventy-seven new cases, as compared with forty-one the previous week. At Camp Jackson, S. C., there has been an increase in the number of cases of meningitis, thirty cases having been reported for the week ending December 15, as compared with sixteen for the previous week. The number of cases of meningitis at Camp Funston continues to decline, only six having been reported for the week. The total number of deaths in all the National Guard divisions was 165, of which 143 were caused by pneumonia. The total number of deaths in all the National Army camps was ninety-seven, of which eighty-nine were caused by pneumonia. In the National Army camps a marked increase in the number of cases of measles has been reported. General Gorgas has sent a letter to the Chief of Staff of the army in which he declares that overcrowding and insufficient heavy clothing are responsible for the high percentage of sickness in some of the camps. It is stated that his recommendations for the improvement of sanitary conditions will be complied with as rapidly as possible.

"Medical Incompetents" to Be Weeded Out.—A special announcement from the Surgeon General's Office, under date of December 21, states that, as a result of the unsuitable conditions found in some of the army camps, steps will be taken to eliminate from the service all incompetent medical officers. In this category will be placed officers not fully qualified to perform their duties because of mental and physical incapacity, bad habits, or laziness. By the provisions of this order, becoming effective December 14, officers assigned to duties that they cannot competently perform, because of unsuitable previous training, will be transferred and tried in other positions. If then unable to do satisfactory work, they will be reported to the Surgeon General as unfit and sent before a board with a view to their discharge from service. Medical officers who have been transferred will be given proper instruction in their new work, and will not be discharged from the service until their superiors are convinced that they cannot become competent within a reasonable time. No action for discharge will be taken until they have failed in two lines of work, viz., the professional care of the sick and disabled and medical field work, the latter including camp sanitation, handling of men, first aid, and transportation of wounded.

Vassar College Prepares to Train Nurses.—Plans have been announced whereby, through the co-operation of a committee of the trustees of the college and the committee on nursing from the Council of National Defense, a school will be established at the college for the intensive training of registered nurses. It is also planned to hold a summer conference of Red Cross home service workers and to establish a Normal Institute under the officers of the American Red Cross.

A Convalescent Hospital at Lakewood.—The Lakewood Hotel at Lakewood, N. J., one of the largest in New Jersey, has been leased by the Government for the duration of the war. It will be used as a hospital for convalescent soldiers. The hotel is in the center of a twelve-acre park, and has 400 rooms, but the building will be remodelled to accommodate 3000 patients. The Government will take possession about the middle of January. A number of hotels in various parts of the country have been taken for the same purpose.

Measles at Camp Devens.—An outbreak of measles among the Depot Brigade at Camp Devens was reported on December 24. Several companies have been placed in quarantine.

Promotions in the Navy.—Secretary Daniels announces that Medical Directors George H. Barber and Edward R. Stitt are to be promoted to the rank of Rear Admiral, in accordance with an act of Congress authorizing two additional rear admirals in the Medical Corps of the Navy. These officers have been selected in recognition of their distinguished services.

THE PATHOGENESIS OF CYSTS AND FISTULAS OF BOCHDALEK'S DUCT.

THERE is at present no valid objection which can be offered to deny the process of evolution of the median thyroid primal elements, the development of which gives rise to Lalouette's pyramid, the accessory thyroids, and certain peculiar formations encountered in the midst of the tongue in quite a number of subjects. The majority of these formations are quite capable of giving rise to cysts, fistulæ, or pathological growths and the embryogenic theory of His is certainly the one which best explains the cases met with. The persistence of the upper portion of the thyreoglossal duct in the embryo is not at all exceptional and may give rise to a tumor or fistula, a fact to which attention was first called by the surgeons. But it may be met with in apparently normal subjects.

The anatomical relations of the duct are usually quite constant. It does not appear to start from the foramen cecum and the subforaminal portion is the part most constantly obliterated. However, a communication seems sometimes to exist through a lacunal tissue, quite analogous to thyroid tissue. From this point the duct reaches the median septum of the tongue, making a slight curve with an anterior concavity, and attains the hyoglossal membrane, in the midst of which it appears to be included. It usually stops at the upper border of the hyoid bone, but when it is continuous with the pyramid of Lalouette, the extension passes behind the hyoid, lying closely against the posterior aspect of the bone. On the other hand, when there is complete occlusion of the duct, the glands of Zuckerkandl-Kadyi (upper portion of the tract) are situated on a plane anterior to that of the hyoid bone, and Lalouette's pyramid (lower portion of the tract) becomes fixed to the posterior aspect of the bone. Therefore, the arrangement in the embryo persists in the adult in the majority of cases.

Independently of the cases with a marked persistence of the duct, the median septum of the tongue may acquire a size and consistency much greater than the normal. When such is the case, a series of cysts, usually superposed vertically upon each other, may be found, spreading the Z-fibers of the raphe apart. These fibers occasionally coexist with some subhyoid glands. It is possible that they are related to the median thyroid primal elements, but further researches are necessary to determine this point.

The foramen cecum is ordinarily represented by a depression of 2 to 3 millimeters in depth, and in about 19 per cent. of the cases it attains the depth of 1 centimeter. Its relations with the large caliciform papilla are variable, but it is clearly the ductus excretorius linguæ of the older writers. These formations, which are regarded as the remains of the median thyroid primal elements, do not develop in the principal duct of Bochdalek which extends to the glossoepiglottic ligament, but in its anterior diverticula.

A pyramid with a bifurcation of its lower end will be found in 5 per cent. of the subjects examined; two incomplete pyramids may also be met with, being probably the remains of the division of the thyrolingual tract which has disappeared. It is rare to find two pyramids reaching upward to the hyoid bone, only two instances being known, one recorded by His and the other by Chemin, and until the contrary can be demonstrated, the same signification can be attributed to them as to the others, by admitting a very early division of the tract.

PAUPERISM AND MENTAL DEFICIENCY.

IN proportion as the social ills are discovered to have pathological foundations more and more of them are being relegated to the care of medical science. Perhaps no greater and older social ill exists than poverty, but the general belief that poverty is caused by disease or disease environment must give way to some modification. At best the conditions are in relation to each other of a vicious circle, with the large probability that disease is caused by poverty rather than the reverse in a people who are unable or unwilling to live up to the necessary conditions of good health. Much of the public, but especially of the private funds is expended needlessly in speculative research into the social causes of poverty and little for somatic causes that must dominate the whole condition. This conception of poverty or pauperism should not be confounded with the occasional instances of individual financial distress calling for assistance, but must concern itself with those individuals who continually live in the subsoil of life, sometime just above extreme adversity, but never far above it. They are usually unable to meet the demands of their own particular society for any period without assistance. They are much below even the lowest social order in which they may live. What savors so much of mental deficiency in them is the unmindfulness of their plight. They are the people who live with the least amount of worry, although it would seem that they ought to have the most of it. They accept the care and assistance continually bestowed

upon them quite as willingly as do the inmates of an institution for mental defectives.

Delinquency in nearly all its phases has for some time been accorded its appropriate place among the mental defectives, by reason of much study and research among those confined in penal institutions or coming before the courts. For delinquents punishment is no longer considered the remedy, but there is a desire to treat them much as one would treat the actual feebleminded confined in institutions. Neither is mere financial relief an adequate remedy for the chronic pauper. He likewise must receive treatment in a clinic or institution. Mental deficiency, delinquency, and pauperism are different manifestations of the same pathological condition. One does not have to be very long in contact with the social work among chronic paupers to see very clearly that one is dealing with a pathological condition and not with what is so vaguely understood as a social condition. Medical missionary work among them is a most important factor in clearing away misunderstanding. Irrespective of the fact of mental or physical inferiority or disorder on which pauperism depends, periodic physical and mental examinations of the chronic paupers under pension would bring to light many remedial diseases or defects; but most of all they would reveal the mental defects among them and would lay the foundation for the proper treatment of this social cancer, pauperism. Members of a family who are plainly deficient are best treated in public institutions for that purpose. Normal members are saved the deleterious effects of contact with the deficient members. Mentally deficient parents allowed to maintain a home under pension do much to keep alive pauperism in future generations, whereas the separation of such parents and the education of the children along appropriate vocational lines may reclaim even defective children.

THE SYMPTOMATOLOGY OF POISONING BY MALE FERN.

The more common disturbances from the administration of overdoses of male fern are those of the digestive tract. The patient's discomfort increases minute by minute. Thirst is intense and is followed by nausea of a violent type, accompanied by a sensation of constriction at the base of the thorax and intolerable pain in the epigastrium. Occasionally the reflex of deglutition is abolished. Following the nausea frequent and uncontrollable vomiting takes place, the odor of the vomitus being that of male fern. The abdomen is distended and rigid. Diarrhea appears upon the scene, the stools being frequent and in large amount, and they may be even involuntary. In the milder cases the patient's general condition is not alarming. However, a quite intense headache may be complained of with labored respiration, slight rise in temperature coinciding with an increased pulse rate, some short attacks of lipothymia, transitory cramps, and somnolence.

In the more serious cases, besides the digestive disturbances, which are very accentuated, there is a long procession of central nervous troubles. These commence with an intense cephalalgia followed by vertigo, the patient staggers, is seized with profuse sweating, and at length falls into a somnolent state bordering on coma, accompanied by persistent cramps and convulsive paroxysms, involving all the limbs, all of which simulates an attack of epilepsy. In some cases, after a short period of excitement, the symptoms assume the aspect of tetanus. The temperature rapidly rises to a high point, while rigidity of all the muscles, particularly those of the jaw, appears and quickly increases in intensity. Trismus is intense, deglutition impossible, the convulsive contractions are very painful and frequently result in opisthotonos. In these circumstances death takes place rapidly, even regardless of the administration of chloral and morphine.

At autopsy the peritoneal surface is rosy, likewise that of the omentum. The stomach usually contains a small quantity of yellow fluid, having the odor of extract of male fern. There is a venous stasis in most of the viscera of the digestive apparatus. The gastric mucosa is red and ecchymotic, while small blood clots are scattered over its surface. The same lesions are found in the mucosa of both the small and large intestine, lesions of gastrointestinal irritation of an intense type being, therefore, the pathological characteristics.

Intoxication by male fern has a marked action on the organs annexed to the digestive tract. There may be jaundice and the urine will be found to contain albumin and casts so that a nephritis may be inferred to exist. Glycosuria has been met with, but according to the experiments of Prévost and Binet the urine reduces Fehling's solution because of the elimination of extract of filix mas and not of the presence of sugar. A generalized edema may arise, particularly marked in the lower limbs, and ascites may be so great as to require paracentesis.

The eye is an organ of predilection for the toxic action of male fern and in many cases there are temporary visual disturbances, such as anesthesia of the cornea, dilatation or contraction of the pupil, and more or less marked amblyopia. In some cases the amaurosis persists and blindness may become absolute. The ophthalmoscopic findings may be negative, but in some cases a marked anemia of the papilla and retina is found, the central arteries being contracted, while the veins are normal. Complete atrophy of the optic nerves follows.

HEART DISEASE IN CHILDREN.

Cardiac conditions may appear in very early childhood, especially among the poor who live under adverse surroundings, and although such conditions are less complex in children than in adults they are by no means less frequent or less severe; they are, indeed, far more frequent than is usually realized. On the other hand, while in adult heart affec-

tions such conditions as chronic degenerations, overwork, many poisons, alcohol, and syphilis operate to produce the high morbidity, these conditions are, for the most part, non-existent in childhood. With these causes removed from comparison it would seem that heart conditions are much more frequent in children than in adults. But many cardiac conditions which would be significant in the adult have no pathological import in the child, nay, they may even be physiological. The whole vasomotor tone, whether central or peripheral, is normally very unstable in the child, and consequent symptoms must be viewed with this fact in mind. Growth in young children is so rapid that not only can tissue defects be bridged but even real heart lesions may be completely overcome by muscle growth. In children one must consider what the heart can do rather than what sounds it emits. Such cardiac symptoms as dyspnea, cough, etc., are not ordinarily produced in the cardiac conditions of childhood because the heart changes are inflammatory rather than fibrotic and degenerative as in the adult. When these symptoms are produced in children the progress of the disease is far advanced, the compensation is very poor, and the outlook accordingly is grave. The best guide in differentiating functional from organic heart murmurs lies in the accompanying constitutional signs and less in certain local differences.

The recuperative powers of the child are always high, but there is a great tendency in child cardiacs to recurrence of the disease originally causing the cardiac condition as well as cardiac complications in almost any other disease from which they may suffer. Valvular lesions are more apt to be multiple in the child than in the adult; likewise hypertrophy and pericardial adhesions are very common. There are likely to be circulatory disturbances of a severe type early in life which greatly retard growth and development. With the recurrence of rheumatic attacks pericarditis is much to be feared and, of course, is very fatal in the young. But in the absence of these grave complications even murmurs may disappear as a result of a complete physical compensation of the defect not merely a dynamic one. There seems to be little doubt that children may recover from an apparently chronic mitral insufficiency or such may become quickly latent. However, if the condition persists beyond puberty in spite of the best conditions, the outlook becomes grave. As soon as the individual is put to the hard work of adult life the heart muscle is unable to rise to the occasion, becomes weakened, and compensation is soon hopelessly broken. Yet death does not usually occur in a short time after the inception of the disease, and when it does occur one may be certain that there was more than a mere valvular involvement, probably a pericarditis or myocarditis. While children may remain compensated for a longer time than adults, when the break in their compensation does come they are much worse off than the adults. They do not so easily recover compensation, and with a failure of compensation death is usually not far off. In cases of adherent pericardium or myocarditis there is likewise only the gravest outlook.

Although no child with cardiac disease should be condemned to chronic invalidism and its education, academic or vocational, should not be neglected, it must be borne in mind that the developmental progress of severe cardiacs is always much retarded both in mind and in body. The life work of the child must be chosen for physical capacity and not for mental ability. Expensive education in the hope that physical incapacity will thus be compensated for is ill-advised. In any but the mildest cases the whole life of the child must be adjusted to a simpler and smoother road.

THE COMPLEX COMPLEX.

A SENTENCE which seems full of meaning occurred in a popular magazine lately. Mr. H. L. Mencken, in his literary review in the November *Smart Set*, discusses the present-day poets. Speaking of one who showed a leaning toward psychopathology, he says: "Politics in poetry is bad enough; when it comes to the subconscious and the Oedipus complex I retire to the woods. . . . The latter (Conrad Aiken) piles up complexes until there arises a sort of complex complex."

This naturally turns one's mind to the psychoanalysts, whose activities have created such a furore in psychiatric circles during the past decade. For the complex is back of all their psychology. Like a malignant spirit it hovers in the background of the neurotic's mind, casting its evil shadow over his life and oppressing his simplest deeds. The treatment of the neuroses and psychoneuroses, in fact, has resolved itself for the psychoanalysts into dragging these complexes into the foreground of consciousness and there disposing of them. For the complex cannot be dealt with in the dim, inaccessible regions it haunts of choice; the sword of the psychoanalyst flashes in vain among the shadows of the unconscious mind and finds no target.

What then must this constant occupation with such subjects do to the psychoanalyst himself? If we suppose that his daily life is spent in the pursuit of complexes. that he plunges and gropes about, with his patient, striving to penetrate the defenses erected against him, wittingly or unwittingly, that he comes to look upon the discovery of the complex as the ultimate object of his work; what the crisis of fever is to the bedside practitioner, what the successful operation is to the surgeon, that the capture of the complex is to the psychoanalyst. Is it any wonder that he becomes preoccupied—obsessed with this endless chase and capture? When all his hours of work are spent in such a pursuit must it not interpenetrate his hours

of leisure and even haunt his sleep? Will not this dominant idea in time come to color all his ideas and actions, amounting almost to an obsession? Will he not in short develop a complex complex? And as it is laid down as an axiom in all literature dealing with the technique of psychoanalysis that the analyst himself must be free from complexes, it follows inevitabily that no man can practise psychoanalysis to any extent without thereby disqualifying himself for its practice. Therefore psychoanalysis is an impossible therapeutic method.

Proposed Ministry of Health in Great Britain.

Major Waldorf Astor read a paper on October 31, 1917, at the British Royal Institute of Public Health on "Health Problems and a State Ministry of Health" (*Medical Press*, November 14, 1917). Major Astor said in part that the first thing required was a central department, and the second was the disentangling and straightening out of the spheres and functions of the 1,800 sanitary authorities, of the 630 boards of guardians, of the 238 local insurance committees, of the 318 local education authorities, and of the 320 new pension committees. He recommended the centralization of power, so far as the public health problem was concerned. They must have one health minister and not three ministers, or even two ministers. One head meant economy of time and effort, economy of man power and energy, economy of the taxpayers' and ratepayers' money. He was in favor of the establishment of the following principles: (1) Of an immediate fusion of the main departments into one ministry. (2) That to this one recognized ministry of health and welfare there should gradually be transferred existing powers from other departments. (3) That all new health developments should, without question, go to this ministry, then they would have got out of the entanglements of rivalries and fruitless negotiations, and would be on the high road to the development of the single policy which the problem demanded. The centralization of authority would undoubtedly do away with a considerable amount of overlapping and confusion of functions, and theoretically should serve the purpose of public health control better, by far, than the various agencies which now exist in Great Britain. The present system has been condemned on the grounds that it is expensive, that it is productive of friction, and that the public health suffers in consequence. In this country, the administration of the public health system is in a large number of hands; there is little co-ordination and there would seem to be little doubt that a Federal Public Health Department, expanded from the present Public Health Service, is quite as much indicated here as a Ministry of Public Health in Great Britain.

Cryptogenic Tetanus.

Since the outbreak of the war we read little or nothing about spontaneous tetanus, although the great number of cases of traumatic tetanus should in theory be attended with an occasional development of the cryptogenic form. In *El Siglo Médico* for October 20 is an abstract of a case reported in a periodical called *Información Médica*. The patient was a man forty-one years of age, excessively nervous, but absolutely free from any wound or abrasion of the surface. He had been engaged in threshing by hand and while bathed in perspiration was forced to sleep exposed to inclement weather. On a particularly cold night he waked unable to open his mouth. There were general malaise and severe pains in the chest, shoulders, and limbs. He was thought to have nothing worse than a severe cold and was given no active treatment. On the following day he was so rigid as to suggest rigor mortis, with a full picture of general tetanic contraction, including the risus sardonicus, opisthotonus, and forcibly flexed limbs. He had fever up to 104° F. and was sweating profusely. The first diagnosis was strychnine poisoning, but this was excluded by the lack of history and course of the symptoms, and was changed to tetanus. There was no dearth of opportunity for infection by the latter, as garden soil, animal excrement, and vegetable débris were all represented in the environment. One could infer that, the tetanus germ having entered into the system by the digestive or respiratory tract, the alternate sweating and chilling served in some way to activate it. But in this case, which was of the most acute type—the patient died on the fourth day of the disease—such an explanaion can hardly hold good. In the "tetanus rheumaticus" of old writers, such as followed exposure, the course of the malady was slow and the prognosis relatively benign. The author makes no mention of an examination of the buccal cavity, and it is quite probable that a port of entry could have existed somewhere about the gums, floor of the mouth, or fauces.

News of the Week.

Federal Control of Vital Statistics Advocated.—In his annual report Samuel L. Rogers, Director of the Census Bureau of the Federal Government, recommends Federal control and supervision of birth and death registration to supplant the present State and municipal systems. The report declares that the United States cannot have a system of vital statistics comparable to those of foreign countries until all the States enact proper laws or until the Federal Government assumes control. He believes the latter course would be most effective. The report says that active preparations are under way for beginning the next census in 1920.

Tuberculosis Hospital Admission Bureau Moves.—The Hospital Admission Bureau, maintained jointly by the Department of Health and the Department of Charities of New York City, through which all admissions to the various public tuberculosis sanatoria and hospitals are handled, has moved into new headquarters at 145 Worth Street, near Center.

Physicians Protest Against Charge of Peddling Narcotics.—Dr. John P. Davin of the special committee on the narcotic drug situation of the Medical Society of the County of New York has sent letters to the Kings and Bronx County medical societies asking them to protest against a recent statement of Judge Cornelius Collins before the Whitman Legislative Committee in which the judge said that the places of street peddlers in narcotics had been

taken by physicians who were amassing large sums from the trade. Resolutions have been framed providing for the appointment of a committee to place the physicians' point of view before the authorities.

Inmates of Asylum Suffer from Cold.—The complete collapse of the heating and lighting plant of the Essex County Hospital for the Insane, at Cedar Grove, N. J., has resulted in a great deal of suffering to the 1,800 inmates of that institution. There have been 24 deaths in 20 days, as against eight for the corresponding month of last year. A letter has been written to the relatives of each patient asking them to remove the patient if possible.

Doctors Protest Against Drug Law.—The public hearings before the Whitney Legislative Committee on the Anti-narcotic Drug Act have continued during the past week. December 21 was given over to hearing the testimony of doctors who seemed to be unanimous in their condemnation of the present law. It seemed to be the general opinion that it was impossible for a physician or a druggist to handle drugs without violating this law and incurring liability to arrest. The inconsistencies of this law were set forth, one that was especially emphasized being that the law insisted upon a physician keeping a record of a prescription or tablets containing one-fortieth of a grain of morphine, while any one could purchase paregoric, which contained a much greater quantity of morphine, without a prescription. Dr. Frank VanFleet, chairman of the special committee on anti-narcotic drug legislation of the Medical Society of the County of New York, appeared before the committee to protest against any law of this nature being formulated without seeking the counsel and advice of the recognized State and county medical societies.

Examination for Assistant Medical Officer.—The Civil Service Commission of the State of New York announces an examination for the position of Assistant Medical Officer, Department of Health Officer of the Port of New York. The position carries a salary of $1,500, together with maintenance. Applicants are required to have a knowledge of quarantinable and venereal diseases. The examination is open only to physicians who are licensed medical practitioners of the State of New York. Requests for application forms must be made to the Civil Service Commission, Albany, N. Y., before January 14, 1918.

The Muskingum Academy of Medicine, at its meeting in Zanesville, Ohio, on December 12, elected the following officers: *President,* Dr. W. F. Sealover; *Vice-President,* Dr. O. I. Dusthimer; *Secretary-Treasurer,* Dr. George Warburton.

The Polk County Medical Society, at a meeting held in Mena, on December 11, elected the following officers: *President,* Dr. W. D. Condally of Hatfield; *Vice-President,* Dr. P. R. Watkins of Mena; *Secretary-Treasurer,* Dr. J. G. Hilton of Mena.

The Southwestern Medical and Surgical Association, which held its fourth annual session at Albuquerque, N. M., on December 9, elected the following officers: *President,* Dr. P. G. Cornish of Albuquerque; *First Vice-President,* Dr. W. Warner Watkins of Phoenix; *Second Vice-President,* Dr. C. G. Duncan of Socorro; *Secretary-Treasurer,* Dr. J. R. Van Atta of Albuquerque; *Trustee for Three Years,* Dr. J. I. Butler of Tucson.

The Medical Society of the State of South Carolina, at its 128th annual meeting held in Charleston, on December 10, elected the following officers: *President,* Dr. Robert S. Cathcart of Charleston; *Vice-President,* Dr. J. M. Green of Charleston; *Secretary,* Dr. G. F. Heide; *Treasurer,* Dr. Daniel L. Maguire; *Librarian,* Dr. F. G. Cain.

The Clarke County Medical Society, at its meeting of December 8, held in Athens, Ga., elected the following officers: *President,* Dr. C. L. Crowe; *Secretary-Treasurer,* Dr. S. S. Smith.

The Duval County Medical Association, at its annual meeting in Jacksonville, Fla., on December 4, elected the following officers: *President,* Dr. Frederick J. Waas, Jacksonville; *Vice-President,* Dr. W. E. Ross, Jacksonville; *Secretary-Treasurer,* Dr. Elmore D. French, Jacksonville.

The Dade County (Florida) Medical Society elected the following officers at its annual meeting on December 6: *President,* Dr. E. M. Jones; *Secretary-Treasurer,* Dr. Hiram Byrd.

Charitable Bequests.—By the will of the late Mrs. Anna Watson Syms of Warren, Pa., the sum of $25,000 is bequeathed to the John Herr Musser Medical Research Laboratory of the University of Pennsylvania.

By the will of the late Dr. William H. Keim an estate of $60,000 is bequeathed in trust for Dr. Frederica Lippert, psychologist to the Municipal Court of Philadelphia, and on her death in equal parts to Hahnemann and St. Luke's Homeopathic Hospitals.

The Late Dr. Guiteras.—At a meeting of the Medical Board of Columbus Hospital, held on December 14, the following resolution was adopted:

Whereas, Dr. Ramon Guiteras has been removed from among us by death, and

Whereas, Dr. Guiteras was for many years attending surgeon to Columbus Hospital and a member of this board;

RESOLVED, That the Medical Board of Columbus Hospital have lost by the death of Dr. Ramon Guiteras a dear friend and a wise councilor and the hospital has lost an efficient and energetic worker. For a period of over twenty years he planned and labored to make the hospital more useful and efficient; and throughout a busy professonal career he gave his services freely to the sick poor. His death will be deplored by members of the medical profession throughout the world, for he had friends among our colleagues in every land. He was especially interested in urology, in which branch of medicine he had attained eminence.

RESOLVED, That the Medical Board of Columbus Hospital extent its condolence and sympathy to the relatives; that these resolutions be spread on the minutes of the board and published in the MEDICAL RECORD, and a copy presented to the relatives.

FREDERICK C. KELLER, M. D.,
Secretary.

Obituary Notes.—Dr. ELIZABETH GARRETT ANDERSON died at her home in Aldeburgh, Suffolk, England, on December 17. She was the first woman to be elected mayor of a town in England, having been elected mayor of Aldeburgh in 1908. The College of Physicians and Surgeons of England at first refused to give her a license, but she received her degree of doctor of medicine from the University of Paris. Shoftly after the beginning

of the war she established a military hospital of 500 beds in London, and in recognition of her services the rank of major was conferred upon her.

Dr. JOHN H. HOXSEY, a graduate of the American Medical College, St. Louis, Mo., in 1895, died of Bright's disease at his home in Spokane, Wash., on December 1, aged 58 years. He served for a time on the State Board of Medical Examiners.

Dr. ADELAIDE LAMBERT, a graduate of the Boston University College of Medicine, in 1884, died after a brief illness at her home in New Haven, Conn., on December 5.

Dr. CHARLES E. NORTH, a graduate of the Buffalo Medical College, in 1898, and Superintendent of the Hospital for Insane Criminals at Dannemora, N. Y., was stabbed and almost instantly killed by an insane inmate of the institution on December 12. He was 50 years of age.

Dr. ORREN CILLEY of Boston, a graduate of Dartmouth Medical College, in 1867, died, following a brief illness, on December 10, aged 77 years.

Dr. WILLIAM JOSEPH HEARN of Philadelphia died of pneumonia at the home of his daughter at Media, Pa., on December 21, within a few days of his seventy-fifth birthday. He was graduated from Jefferson Medical College in the class of 1867. He was for many years in his early career anesthetizer for the late Professor Samuel D. Gross, from 1877 for a number of years chief clinical assistant in the outpatient surgical department of Jefferson Hospital, later surgeon to the hospital, eventually clinical professor of surgery and finally emeritus professor. He was also for many years one of the surgeons to the Philadelphia General Hospital. He was a member of the Philadelphia Academy of Surgery and of the American Surgical Association.

Dr. JOHN R. STEVENSON died at Haddonfield, N. J., on December 21 at the age of 83 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He was a member of the Camden County Medical Society and the New Jersey State Medical Society and a fellow of the American Medical Association. He served as a surgeon in the United States Army during the Civil War.

Dr. FRANK WENTWORTH PLUMMER died of erysipelas and bronchopneumonia at his home in Malden, Mass., on December 15. He was graduated from the Harvard Medical School in 1895.

Dr. JAMES E. SHANNON of Sharon, Tenn., died of blood poisoning at St. Thomas Hospital, Martin, Tenn., on December 1, aged 52 years. He was a graduate of the University of Louisville Medical Department in 1887.

Correspondence.

THE LAST ILLNESS OF GEORGE WASHINGTON.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I am inclosing copy of a letter which fell into my hands a short time ago, giving very definitely the disease from which General George Washington died. In all the histories that I have read of George Washington it is stated that he died from pneumonia, or quinsy. From the enclosed letter you will see that he undoubtedly died from diphtheria. This letter may be of interest to medical men, and should you so desire you can publish it in the RECORD.

J. A. NYDEGGER, M. D.,
U. S. Public Health Service.

ALEXANDRIA, VA., January 10, 1800.

Dear Sir:

I thank you for your letter of the 21st ultimo, which I should have acknowledged earlier, but from a remote expectation of seeing you in Philadelphia this winter, but which I have ultimately entirely relinquished.

The general anxiety and consequent conjectures which you speak of relative to the case of General Washington was expected, and produced the statement of the disease and treatment which I presume you have seen in the public prints.

The statement which I drew up at the request of Dr. Craik is as ample perhaps as it was necessary or proper to present to the public eye, though it may subject us all to a censure from which I might claim an exemption.

As soon as it was found that the last bleeding which was copious was ineffective, and believing on all hands that no considerable accumulation if any had taken place in the bronchi, I proposed to perforate the trachea as a means of prolonging life, and of affording time for the removal of obstruction to respiration in the larynx, which manifestly threatened speedy dissolution. It was received at first, at least by one of the physicians, with a seeming acquiescence, but apathy at first appeased the effort of further consideration, and finally a firm opposition to the measure. I urged with all the arguments in my power the propriety and expediency of the proposed operation and agreed to be answerable for all the consequences in case of its failure, which constituted the whole force of Dr. Brown's objections, but to no effect.

You recollect the reluctance with which Dr. Craik acknowledged the existence of croup among the children of this place, and the commonplace term sore throat which he chose for that disease, this will account for the indifferent name "Inflammatory quinsy" which he gave to the General's complaint before my arrival at Mount Vernon. You will readily suppose, I was inclined to be more explicit, and not being very fond of technical terms was satisfied with calling it croup. The other gentlemen studiously avoided giving it any name, but agreeing with me that the larynx was evidently the seat of the disease.

I waived all discussion upon the subject and upon this point while the General was living. After this unhappy event, and before we separated, I called their attention to the subject, by stating the necessity of agreeing upon some appropriate name for the disease, observing, at the same time, I had seen three cases, fully avoiding to repeat the name I had given it, and yet declining to give it another. Dr. C. spoke of "Inflammatory quinsy." I objected to it as indefinite. I offered the choice of Cynanche Trachcitis, stridula suffocatis, or laryngea, and they chose the former. I mention these little incidents because I know they will be interesting to you.

Since you left Alexandria, I have had nearly forty cases of the croup, three adults and the remainder in children, from 1 to 10 to 12 years. Bleeding ad deliquium has been my uniform remedy, and has been employed with uniform success. In two cases only it appeared necessary to repeat the bleeding as at first, and I did so.

You know my pathological ideas of the complaint. I consider it as an inflammatory tumefaction of the larynx, and would therefore call it Cynanche Laryngea. There are however some varieties of the disease. I have seen three cases where it was seated in the trachea, occurring from about half an inch below the cartilaginous prominence downwards. Has this complaint been unusually prevalent this winter in Philadelphia? What remarks are made among the Faculty concerning us, in the General's case, since the publication of the statement?

I am as heretofore,
Your real friend,
(Signed) Dr. CULLEN DICK.

To Thomas Semmes,
A Medical Student at the University of Pennsylvania,
Philadelphia.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

THE PASTEUR INSTITUTE AND THE WAR.

PARIS, November 22, 1917.

IN a recent interview Dr. Roux detailed how the Pasteur Institute had been reorganized to meet successfully the extraordinary demands made upon it by the unusual conditions of the present war; he explained that before the war its personnel numbered about 200 individuals, and of this number 126 were mobilized in August, 1914. This group comprised 41 doctors, 3 chemists, 6 veterinary surgeons, 76 officers and soldiers. The laboratories for study and teaching were closed, and only a few laboratories for research were allowed to remain open. Some of the services, which could not be allowed to be interrupted, were kept going by a very limited number of people. Such were the departments of rabies, diagnosis (examination of blood preparations), vaccines (typhoid and cholera), vaccines for animals, and the serotherapeutic service. The war has, however, not stopped activity at the institute; it has simply transformed it into a veritable factory for the Health Department of the army and under its control.

The experience of all armies has demonstrated the fact that epidemics have always been serious, and these can be avoided only by the protective measures prescribed by science, such as disinfection, bacteriological investigation, the purification of the water supply, timely and precise diagnosis of infectious diseases, search for germ-carriers, and preventive vaccination. In France each army, each military region, has been supplied with laboratories for bacteriological and chemical research in connection with prophylaxis. More than this, each hospital for contagious diseases has a bacteriologist and a laboratory for his work. The number of military laboratories is now about 200, which are supplied with what is necessary by the Pasteur Institute. Even many of the laboratories of the Allies are supplied by the institute.

There was never a war in which the epidemics were so rare as the present one so far as France is concerned. Typhoid fever, which was rare at the beginning of the war, began to be serious when the front was fixed and the combatants remained in the trenches or near at hand. It was checked, however, by vaccination, and this was the case with cholera also. The institute delivered to the French troops about nine million doses of vaccines, and helped the Serbian army also in fighting typhoid and cholera. Vermin have tormented the soldiers considerably in billets and in the trenches, but the institute prepared sachets containing certain essences which were placed in the clothing, and this method was effectual in either killing the insects or driving them away; many hundreds of thousands of these sachets have been sent to the front. Malarial fevers were common in the East and caused many of the men to be sent home for treatment; this necessitated the establishment of a number of services for examining the blood of the patients. The same may be said as to dysentery.

From the time of the first battles of the war the number of wounded was considerable, mostly caused by explosion of shells, and tetanus followed frequently. At that time there were only about 150,000 doses of antitetanic serum in the reserve stock, and so the workers in the institute had to get to work and increase the output. In ordinary times fifty horses sufficed for producing this serum. This figure jumped up to 600 horses, and the army was supplied with more than four million doses of this serum.

The negro troops on coming to France suffered considerably from pneumonia, but a special vaccine was eminently successful in combating this disease. Bites of serpents were serious in the Orient, but the institute had a serum for that trouble, which produced the best results.

The horses bought in foreign countries were rather commonly affected with glanders, but the workers at the institute coped with this successfully. Lymphatic diseases among horses rendered a large number useless for work for months at a time. A special vaccine, however, was furnished, which is now being very widely successful. The poisonous gases employed by the enemy in their nefarious conduct of the war brought the institute chemists plenty of work, and their researches developed measures which have given wonderful results.

1. Hodgkin's Disease: A Report on the Cases Observed at the Collis P. Huntington Memorial Hospital from April, 1913, to July, 1916, with Special Reference to Treatment with Radium and the X-Ray.—Channing C. Simmons and George Benet cover a period of a little over three years in this report. During this three-year period, 31 cases, clinically diagnosed as Hodgkin's disease, applied for treatment. Three of these proved, on microscopic examination of the glands, to be lymphosarcoma. Of the remaining 28, specimens were available for study in 20, one of which proved to be metastatic carcinoma, while reports of the glands removed in other hospitals were obtained in 3. They believe there is a distinct disease of the lymphatic tissues called Hodgkin's disease, which can be separated from Banti's disease, lymphatic leukemia, etc. The diphtheroid bacillus was found in two out of the three cases in which it was sought, and it probably can be demonstrated in many of these cases. Inoculation experiments done on guineapigs and three monkeys were negative, and a piece of gland transplanted subcutaneously in the same patient from whom it was removed, atrophied and disappeared, which they consider an important observation, as a fragment of sarcoma or carcinoma treated in a like manner would probably have grown. This last fact is rather against the tumor theory. Microscopically, the glands were typical of the Dorothy Reed type of Hodgkin's disease, and were similar to the cases reported by Reed, Longcope and Simmons. The cases of lymphosarcoma presented microscopically an entirely different appearance, and in one case that came to autopsy no gland examined had the slightest resemblance to Hodgkin's disease. They further report that clinically, Hodgkin's is a fatal disease, that runs an acute or chronic course, little affected by treatment as regards the ultimate fatal result. It

may usually be suspected, but there is no way to make a definite diagnosis without a microscopic examination of one of the glands. It cannot be differentiated clinically from certain cases of lymphosarcoma, tuberculosis, or even inflammatory glands. In their series the blood picture was not constant, and although they do not feel able to make a diagnosis on it alone, it is often quite suggestive. As regards treatment, radium and the *x*-rays have a distinct beneficial effect, radium being of more value than the *x*-ray. With treatment, the glands diminish in size, and the general condition improves. The relation between the treatment and the improvement is definite, and is seen in from one to three weeks after the first application of radium. They have no cases that can be called cured, but the patients are comfortable and able to attend to their duties until nearly the end of the disease. They do not know if the fatal termination has been much postponed, as the cases most benefited may have the chronic form of the disease. The treatments should not be limited to the palpable glands, as is usually the case, but should be directed against the lympthatic areas of the body, the mediastinum, abdomen, etc., from the first.

6. Laryngeal Stenosis as a Complication of Measles.—M. Ford Morris calls most decided attention to laryngeal stenosis as a complication of measles which requires vigorous and quick attention. The symptoms are those of croupy cough, increasing dyspnea and pallor, and retraction of the epigastrium and lower intercostal spaces. A membrane may or may not be visible. It will be seen that these symptoms closely resemble those of laryngeal diphtheria. His experience with these cases has been gathered from the wards of the Willard Parker Hospital and some of these patients enter the hospital with nose and throat cultures negative for *Bacillus diphtheriæ*, while others have positive cultures; some react to the Schick introdermic test, while others do not. Morris quotes Parke, of the Department of Health Research Laboratory, as stating that "positive cultures of a diphtheroid organism and a diphtheritic looking membrane do not necessarily mean that the case is diphtheria," and also that he "does not believe that diphtheria ever occurs in a person who has a negative Schick." If the diphtheria bacillus does not cause this laryngeal condition, either the streptococcus or staphylococcus is the "root of the evil." Morris considers this condition of laryngeal stenosis is a too frequent and a very serious complication of measles and that the onset of a croupy cough should be the signal for vigorous treatment. Intubation should be tried, even though it failed to relieve in the cases cited above. Large doses of diphtheria antitoxin—15,000 to 30,000 units—should be given, in the writer's opinion, even in cases with a negative Schick, and in the latter cases, for the purpose of satisfaction of conscience, if nothing else. If a positive blood culture of the streptococcus or staphylococcus can be obtained, vaccine therapy, preferably autogenous, will be logical.

6. The Syndrome of Mild Peristalsis.—Walter C. Alverez brings out the fact that gastrointestinal symptoms are motor and not secretory and that they arise when the normal progress of the food is disturbed. He includes four types of motor disturbance: Speeding up of the current; slowing; complete stoppage, and reversal. It is to the last type of motor disturbance, namely, reversal or peristalis, that he gives special attention. Vomiting, regurgitation, heartburn, belching, nausea, coated tongue and foul breath, globus, a feeling of fulness after taking a few mouthfuls of food, and biliousness all can be the result of mild reverse peristalsis in the stomach or intestines, and he gives this as aften a cause of these conditions. Most of these disturbances are due to ripples coming up the tract. His records show that ripples can come down the intestine long distances without forwarding the contents and can then break into strong waves which rush material along before them; he therefore considers that similar ripples can travel upward in the wall of the bowel until they show themselves as waves in the stomach and esophagus. When the gradient of forces in the tract is poor, waves can probably travel in either direction. When the stomach is full and active, it will be easier for waves to proceed aborally; when the stomach and small intestine are empty and the colon is full, the waves will more easily ascend. Also, the gradient may not be upset to the same extent in all parts of the tract, as, for instance, reverse waves might be present in the stomach and normal ones in the bowel. We cannot expect to see much reverse peristalsis with the roentgen ray, because, normally, the food cannot be followed in the small intestine after it leaves the duodenum, and before it reaches the terminal ileum. But actual reverse transport of material has been observed in those parts of the tract which are accessible to roentgenographic study. Twice Alvarez has observed definite reverse peristalsis in stomachs free from organic disease, and subsequent operation revealed the cause to be, in one, appendicitis, and in the other, duodenal ulcer. More important than visible reverse waves are the reversed impulses that hold back the barium here and there in the tract, in spite of the fact that the muscle is active, and the tube ahead is unobstructed. Alvarez has thus tried to direct the attention of physicians to what he terms disturbed physiology, of which these examples cited are instances. Thinking in such terms will make for better therapeutics, produce less tinkering with medical means in these types of cases, expressed by gastritis, hyperacidity, or biliousness, and the surgeon will receive the case promptly as should be. If such radical treatment is inadvisible or impossible, the physician will use a smooth, cellulose-poor diet, which will flow more easily along the impaired gradient. Later resting and overfeeding can be tried to improve the condition.

1. Experiences in Colony Treatment and After-care.—G. Sims Woodhead and P. C. Varrier-Jones give some

of the experiences gathered and some of the results obtained after the two years' existence of the Cambridgeshire Scheme of After-care—a sanatorium method of treatment. They sum up the advantages offered by this method of treatment as follows: Prolongation of the period of treatment with more intensive, because more interesting and better graduated, treatment; the utilization of suitable occupations in such treatment even during the earlier stages of residence in the colony; the continuation of training and the consolidation of the improvement already gained during the preliminary stages of treatment, and more personal supervision and immediate encouragement. The utilization to the best advantage of the funds drawn from (*a*) the National Insurance Commissioners; (*b*) the rates; (*c*) the Pensions Ministry; (*d*) Approved Societies; (*e*) voluntary subscribers, and the pooling of the advice and countenance of these various authorities, bodies and individuals. The preparation and encouragement of the patient to re-enter, under more favorable conditions, on the struggle for a livelihood without having to contend against the drawbacks attending overwork, overstrain and anxiety. The moral encouragement afforded to the patient by the knowledge that these favorable conditions, already tried and successful in the case of others, are available in his own special case. The gain to the community of a productive member in place of a useless consumer. It may be objected that this member is producing but 50 per cent. or 60 per cent. of his full or original amount, but to this it may be answered that this 50 per cent. or 60 per cent. may represent considerably more than the full capacity of many a healthy worker. The segregation and isolation of "centers" of massive infection and the bringing down to a comparatively safe dilution, of less—but still under certain conditions—dangerous quantity. The education of patients in the "ritual" necessary for their own "nutrition," maintenance in, or restoration to, health and strength, and especially the knowledge of how to render themselves harmless to themselves, their families and their friends. The inculcation of a feeling of moral and physical self-respect involved in the knowledge that they are being cared for, not out of charity, but because their fellows—the State or community—recognize that they, members of this community, have fallen by the way, not as a result of their own misdoings, but because surroundings were unfavorable and conditions adverse, and that these righted they still have a chance of making a success of their life and work.

3. Direct Transfusion of Blood.—Alfred G. Hull finds that while the advantages of direct transfusion are so apparent, this treatment does not appear to be in such frequent use as it merits. Apart from its obvious indications in cases of severe hemorrhage, it would appear to be a valuable treatment for severe sepsis and shock. How far the alteration of the blood in cases of shock determines the result is at present uncertain, but the effect of healthy blood upon the tissues of such patients appears to be worthy of consideration. Transfusion seems to be a more scientific remedy than the empirical injections of antiseptics into the blood stream. The difficulty of obtaining some one willing to submit to an operation entailing ligature of an artery he considers the only bar to a much greater use of this treatment. The operation is simple and can be performed without the use of special apparatus. To produce the best results the transfusion of blood must be direct from artery to vein, as in this way only can clotting be prevented with certainty. The only disadvantage of this method is that the amount of blood transfused cannot be measured, but this is outweighed by the safety and simplicity of the method, and moreover the amount of blood which flows before the donor becomes faint is fairly constant. In preparing for the operation the left hand of donor grasps the arm of the patient just above the elbow, bringing the donor's radial artery in close proximity to the patient's median basilic vein. Then an incision about 2 inches in length is made in the patient's arm over the median basilic vein. A similar incision is made over the radial artery of the donor. The artery is cleaned for about an inch, and the lower end of the artery in the wound is clipped, digital pressure is made over the brachial artery, and the radial is cut above the clip. The end of the radial artery is pulled out of the wound, and a traction suture is tied through the wall of the artery. Two probes about an inch apart are passed under the vein for hemostatic purposes. A small cut is made into the vein (2 mm. in length); through this the needle bearing the traction ligature from the radial artery is passed. The needle emerges from the vein an inch above the incision. A second suture is now passed through the wound in the vein; this suture is used to close the vein when the artery has been inserted. By drawing upon the traction suture the artery is drawn into the vein, the vein suture is tied, and the probes and digital pressure removed. The blood is allowed to flow until the donor feels faint. The artery is then clipped, pulled out and ligatured. The whole procedure is carried out under local analgesia. There is no serious mutilation of the donor by this method, and the elasticity of the artery makes it an efficient cannula, while a considerable length of vessel becomes available through a comparatively small wound.

La Presse Médicale.

The Wassermann Reaction in Malaria.—De Jong and Martin mention the idea that in certain sectors the occurrence of positive Wassermanns has caused the suspicion that malaria might be in part responsible. This obtained first on the Eastern front and later in the XV region on the west. During the past 6 months the authors obtained 300 positive Wassermanns in the Nice medical sector, and of the subjects at least two-thirds suffered from old or recent malaria. In any problem of this sort technic is all important and the authors first employed the Alfred Bauer-Hallion method (unwarmed serum). The natural hemolytic power and complement-fixation reaction of the serum to be tested are determined with the utmost regard for every detail and a comparison made with the results of the classical test. In regard to malaria the seroreactions were controlled by blood examinations for the presence of the plasmodium. Save when there is an actual invasion of the blood by the latter, in association with a clinical manifestation (chill, fever) there is every reason to believe that the serodiagnosis of syphilis is not prejudical. During the acute malarial outbreak the reaction may be disturbed as in any febrile state and should not be attempted at that time. The question of vital importance, "May a non-syphilitic malarial subject give a positive Wassermann?" cannot be answered offhand. It was certainly absent in a number of cases.

Contribution to the Study of the Cardiopulmonary Circulation.—Colleville alludes first to the great number of convalescents with poor circulation at the rear of the fighting front. These men will later return to fight. According to the dominant symptom they are classed as cardiacs, enterocolitics, neurasthenics, etc. They suffer from past defective alimentation in the trenches, past alcoholism, syphilis, ordinary infections, and are menaced by tuberculosis. Among them are pneumopaths, subjects with compensated mitral lesions, etc., who require measures for increasing the lesser circulation. The myocardial energy, the resistance in the circulation and the nervous system form a triad of factors to be borne in mind. Certain drugs,

notably diuretics and vasodilators, diminish the resistance in the vascular circuit and aid the cardiac tonics. Terpine or benzoate of soda, "bronchial diuretics" and codeine form a cupneic combination. Quebracho and lobelia act chiefly on the lesser circulation. Caffeine and adrenaline are good stimulants for the same. Strophanthine and lobelia make an excellent cupneic combination. Sparteine and valerian combine a mild circulatory regulator and nerve sedative. Strychnine and sparteine form an excellent stimulant of the lesser circulation. Theobromine is a wonderful diuretic and sodium iodide lessens pulmonary stasis by reducing the viscosity of the blood. Fibrolysis aids by breaking up pleural adhesions.

Finska Lákaresällskapets Handlingar.

August, 1917.

Congenital Giant Growth of the Extremities.—Kalima describes two cases of congenital giant growth of the upper extremities. One case was complicated by a large lipoma which extended from the palm of the hand half way up the upper arm. In extirpation of the mass it was noted that while it was sharply limited in places it also presented a diffuse quality. The other case was uncomplicated, of bilateral type, but with marked muscular hypertrophy on the right side. The author concludes with others that the Fischer types of gigantism of the extremities should be excluded as not genuine. There are, he believes, two types, one uncomplicated, the other complicated by tumor formation (lipoma). The latter is rejected by Fischer as spurious.

On Diseases of Nutrition in Nurslings and Their Treatment with Albumin Milk.—Nystén first discusses the pathogenesis of these affections and the general principles of treatment, especially with Finkelstein's albumin milk. He next gives the results of treatment in the pediatric clinic at Helsingfors with this product. Albumin milk has been used in this clinic since 1910, and in all 180 children have been treated. There were comprised 72 cases of dyspepsia, 32 cases of decomposition, 42 cases of alimentary intoxication, 18 cases of disturbed nutrition following infection, 10 cases of congenital debility and 6 cases of acute enterocolitis. No case is considered which was not under treatment for more than 5 days. The general results of albumin milk treatment were good. The quality of the stools soon improved, temperature and pulse became normal and the general state improved. In several cases success was obtained after other diet plans had failed. In congenital debility alone were the results not very satisfactory, probably because the protein and fat content of albumin milk is too high. For this class buttermilk should be better.

Meningitis Serosa.—Toivonen reports 7 cases of this affection which occurred in the Deaconesses House, Helsingfors. With the exception of one hyperacute case in which death occurred before treatment could be instituted the results were favorable. The immediate cause appeared to be exposure, excitement, bodily or mental over-exertion and parturition. Other factors were acute infectious diseases, tuberculosis and trauma. Symptoms were those of brain pressure (headache, vertigo, optic neuritis, choked disks, paralysis of ocular muscles), increased reflexes, disturbances of sensibility and consciousness. Differentiation from brain tumor and from other forms of meningitis is often extremely difficult and lumbar puncture is often of value. Variation in intensity of symptoms points to serous meningitis. Precocious appearance of choked disks and ocular paralysis is also very suggestive. Treatment consists chiefly of lumbar puncture and mercurials.

Berliner klinische Wochenschrift.

October 1, 1917.

Orthopedic Prophylaxis in Wounds of Warfare.—Meyer insists on the necessity of early consideration of the ulterior condition of limbs presenting recent injury. Just so soon as the "vital" indications have been attended to, it is incumbent upon the surgeon to prevent the occurrence of deformity. Meyer is of the opinion that immobilization should be done away with as soon as possible, but if it is absolutely necessary, it should then be carried out by changing the position of the limb from time to time, always bearing in mind that the extensor muscles atrophy with greater rapidity than the flexors. For example, the crural quadriceps is particularly prone to atrophy and for this reason it is indicated to make a window in the plaster cast for the purpose of electrical treatment of the msucle in question. If contracture appears to be inevitable, one should take into consideration the profession of the patient, as well as his wishes, as a guide to subsequent treatment. In the case of the upper limb, the position in abduction of the shoulder is by far the most suitable. The forearm should be placed in a position intermediary between pronation and supination. In the case of the hand, it is better practice to place it in hyperextension, which will assure the best function of the fingers in case secondary contraction should ensue. The saddest results have been noted, so far as function is concerned, in the hand, which is only too often seriously damaged by immobilization of the forearm and fingers. The writer is of the opinion that puncture of the fluid collections in the knee joint should be made much more frequently than is done, because it avoids coagulation and organization of the clots, which is the starting point of very obstinate adhesions. All splints should be made as simply as possible, and the writer has employed with advantage spiral springs which produce a continued traction on the particular joint undergoing treatment.

Chemotherapy of Lupus, Its Results and Its Future.—Strauss reviews the various chemical medicaments which have been essayed in the treatment of tuberculosis. Salvarsan and cyanide of gold have offered some encouraging results. The writer has obtained the best results by the external use of copper, combined with "lecutyl," in order to obtain penetration of the drug into the lipoid substance of Koch's bacillus. This local treatment is applicable not only to lupus, but also to tuberculous processes of the various mucosæ, likewise the surgical tuberculoses. The writer fancies that copper also acts by stimulating immunization.

Wiener medizinische Wochenschrift.

October 6, 1917.

Clinical Aspects and Pathogenesis of Paratyphoid A and B.—R. Loewy, summing up a recent article on paratyphoid A, the writer says: "Three principal types can be admitted, according to the gravity and duration of the process. A severe type, with a high temperature for two or three weeks; secondly, a type most benign in character, undergoing its evolution in one or two weeks, and, lastly, a third type, which can be placed between the other two, and is characterized by a markedly remittent form of temperature. More than 50 per cent. of the cases begin with a chill, and the same may be said of relapses. An initial symptom often met with is violent neuralgic pains in the lower limbs. The spleen is indurated and hypertrophied in almost all cases. Roseola is not present in hardly 33 per cent. of cases. Therefore, although paratyphoid A possesses some characters belonging properly to it, it must nevertheless be admitted that in the majority of cases its symptomatology is that of typhoid fever." Next passing to the report of some cases of paratyphoid B, the writer points out the great similarity of this process with those of paratyphoid A and typhoid fever. Agglutination generally commences in the first or second week while the percentage is commonly greater, reaching in some cases 1/16,000. The hard tumefaction of the spleen is usually very marked, while the roseola is frequently abundant, covering a large area and extremely scintillant. Finally, Loewy, insisting on the frequency of mixed infections, offers considerations of a theoretical nature, in order to explain the fact that since the beginning of the war typhoid fever has gradually lost its customary virulence, while paratyphoid A and B appear to have increased in severity. He fancies that this fact may be attributed to the local immunity acquired against Eberth's bacillus, this histogenous local immunity increasing the susceptibility of the organism to infection from paratyphoid A and B. The writer, however,

maintains all necessary reserve in regard to this (to him) satisfactory interpretation.

Münchener medizinische Wochenschrift.

The Roseola of Typhoid Fever.—E. Fraenkel recalls the fact that he has already shown that the roseola of typhoid fever is accompanied by similar vascular phenomena in the various viscera excepting the pulmonary tract (*Münch. med. Woch.*, 1914, page 2354). He performed biopsies, both on lesions, in full efflorescence on exanthemata produced by Esmarch's band during the stage of convalescence. The histological lesions occur in the subcutaneous tissue and in the arteriolæ, the veins not being involved. The lesions consist in periarterial nodules, while the endothelium is likewise pathologically changed. The walls of the arteriolæ offer a hyaline transformation. The nodules are composed of fusiform cells, a few hyaline thrombi may be encountered in vesicles. The evolution of the periarterial nodules appears to terminate in a connective tissue metamorphosis. There are no permanent vascular disturbances because the arteriolæ remain patent, while they also offer a mutual substitution in case of occlusion.

The Action of Mercury on Syphilis.—Lomholt and Kissmeyer have wished to ascertain the quantity of mercury circulating in the blood of subjects undergoing an antisyphilitic treatment. The maximum amount obtained by the writers was found by them to be 33 milligrams mercury per liter of serum. They made a broth composed of ascitic fluid and meat to which they added mercuric chloride at a corresponding dose and found that at this concentration the antisyphilitic treatments realized in man were quite powerless to prevent the development of the *Spirochæta pallida*. The writers conclude, with all the necessary reserve required in *in vitro* experimentation, that mercury does not act directly or chemically from the mere presence of its ions in the blood.

October 4, 1917.

Treatment of Tabes Dorsalis by Neosalvarsan According to Leredde's Method.—Karczag offers the results obtained by the above mentioned method of treatment as described in 1913 by Leredde ("Études sur le serodiagnostic et traitement de la syphilis"). The writer followed this technique closely and no serious complications were observed in 18 cases so treated. The writer noted some disturbances in the pulse and he therefore advises keeping the patient in bed until the end of the treatment. The results arrived at are tabulated as follows:

	Cases.	Improvement Marked.	Satisfactory Improvement.	Without Effect.	Aggravated.
Lightning pains	14	8	..	4	..
Paroxysms	3	..	3	..	..
Headache	13	7	5	..	..
Insomnia	3	2	1	..	..
Vesical disturbances	12	4	8	..	..
Ataxia	6	3	3	..	..

Homo- and Autografts in the Regeneration of a Divided Nerve.—Forsmann has noted the uncertainty which at present reigns as to the process of nerve repair by suture, whereas, animal experiments have shown that the best method is certainly that proposed by the writer himself, namely, the interposition between the divided ends of a nerve or a fragment of a nerve (saphenous or intercostal for example) taken from the patient or from another subject (homo- and auto-transplantation). The mechanism of the process should be sought for in a neurotropism to which central end is subjected, this resulting in a proliferation of the neoformed fibers in a determined direction. Cahen has resorted to the same method and obtained one brilliant result out of three cases in which he attempted this technique.

Artificial Pneumothorax as a Diagnostic Measure in Pulmonary Neoplasms.—Schroeder has resorted to this procedure, which is not dangerous, and may even be favorable for the patient since it places the progress made by pulmonary growths under the control of the observer. It is to be noted that a tumor can sometimes be percussed by this means, so that an early diagnosis can be made.

Syphilis and Maleness of Offspring.—Giraulde and Tissier dispute the teaching that pregnant syphilitic women rarely give birth to boys. Their own statistics show the very opposite.—*La Presse Médicale.*

Simulation of Tuberculous Tissue by Syphilis, Leprosy, and Sporotrichosis.—According to Hoffmann not only these three affections, but Boeck's sarcoid as well may present in skin lesions the histological characteristics of tuberculous tissue.—*Deutsche medizinische Wochenschrift.*

War Amenorrhea.—According to Pok the poor diet, overexertion, and worry of the war are responsible for suppression of the menses in certain women. At first he curetted, but soon became convinced that no actual pathological state was present.—*Zentralblatt für Gynäkologie.*

Ethylic Intoxication and the Temperature.—The toxicity of alcohol to fishes increases progressively with the temperature. Thus it excites at a low level—near 0° C.—and depresses at a high temperature. Linossier sees here a possible objection to alcohol in fevers.—*La Presse Médicale.*

Uterus Perforation.—In the course of a curettage *post abortum* the practitioner perforated the uterus, and a loop of intestine which entered the cavum uteri was mistaken for the cord. Resection, suture, and reposition of the gut were followed by recovery.—*Correspondenz-Blatt für Schweizer Aerzte.*

Chronic Parotitis from Plumbism.—Laignel-Levastine and Nogues report the case of a plumber aged 40, who had never secreted parotid saliva (he had begun his apprenticeship at 16) and whose parotids were hypertrophied in characteristic pear shape. He suffered from general plumbism.—*La Presse Médicale.*

War Amenorrhea.—During the present year three articles on this subject have appeared in the *Zentralblatt für Gynäkologie.* Hunger, care, and overexertion are known to be able to cause amenorrhea, so that the experiences in the present war offer nothing new.—*Correspondenz-Blatt für Schweizer Aerzte.*

Precipitate Labor and the War.—Nassauer believes that the average duration of labor is less than before the war. He associates this phenomenon with war amenorrhea, in the view that as a result of nervous tension the hypophysis secretes its hormone in excess.—*Nederlandsch Tijdschrift voor Genceskunde.*

Fat Thrombosis in the Digestive Tract.—Nauwerek found in three autopsies fatty concrements in the large intestine which evidently represented molds of certain ulcerous cavities or diverticula at a higher level. The death agony with its fall of temperature had evidently set these bodies free.—*Zentralblatt für immere Medizin.*

Treatment of Congelations with X-Rays.—Wachtel obtained good results when the rays were used early in superficial freezes. In deep freezes sloughing seemed to be accelerated and limited moist gangrene was strikingly improved. The rationale in the author's opinion is an induced therapeutic hyperemia.—*Correspondenz-Blatt für Schweizer Aerzte.*

Fruits and Legumes in the Propagation of Infectious Diseases.—Russ sprinkled cultures of the bacilli of typhoid fever, dysentery, and cholera on plums, peaches, and salad vegetables, etc., and learned that these organisms remained alive for long periods. Sunlight appeared to exert no bactericidal action.—*Office International d'Hygiene Publique.*

Action of Adrenalin on the Digestive Tract.—Loeper and Verpy experimented with 8 standardized subjects and found that adrenalin increased both total and free HCl in the stomach; increased the gastric motility in hypotonic subjects, and acted as a sedative in over-frequent and intense motility. The digestive passage is accelerated.—*La Presse Médicale.*

Book Reviews.

THE ORGANS OF INTERNAL SECRETION. Their Diseases and Therapeutic Application. A book for general practitioners. By IVO GEIKIE COBB, M.D., M.R.C.S. Late Assistant to Out-Patient Physician, The Middlesex Hospital. Price, $2.00. New York: William Wood & Company, 1917.

THIS book is founded upon articles which appeared in the *Medical Press and Circular* in 1916. The author has omitted the exhaustive accounts of laboratory research, which cumber most of the books on internal secretion, and he has preferred to point out, for the general practitioner, the rôle which the ductless glands play in promoting bodily health and the various morbid states of health in which organic extracts may be utilized with success. The chapters on the thyroid and parathyroid glands take up the first four chapters; then follow chapters on the pituitary body, the adrenals, the pancreas, the sexual organs and their internal secretions, and the internal secretions of digestion. The therapeutic application of hormones is summarized in Chapter X, and those readers who are mainly concerned with the therapeutic aspect will find in this chapter a useful summary of the subject. The final chapter is devoted to a survey of the whole subject and deals with the present position of hormone therapy. The book is readable and up to date, and its handy size will attract many readers who would be repelled by a much more bulky volume.

CLINICAL SURGICAL DIAGNOSIS FOR STUDENTS AND PRACTITIONERS. By F. DE QUERVAIN, Professor of Surgery and Director of the Surgical Clinic at the University of Basle. Second English Edition. Translated from the Fifth (French) Edition by J. SNOWMAN, M.D. Octavo of 842 pages, with 604 illustrations and 5 plates. Price, $10.00 net. New York: William Wood & Company, 1917.

IN its field de Quervain's book on clinical surgical diagnosis occupies a field comparable to that of Lejar's "Urgent Surgery" and Osler's "Practice of Medicine" in their respective fields. That being the case, how can a reviewer do justice to the book in the short space that is of necessity allotted to him?

De Quervain's long experience as a teacher and consultant has eminently fitted him to cover this extensive subject—a subject where the author must himself separate the wheat from the chaff and not confuse the student by including a mass of inconsequential detail. For conciseness and clarity of description this book, in our opinion, is unexcelled. According to the author, it is designed to serve as a guide to the student in the vast field of surgical diagnosis which they are required to explore, and to recall to the practitioner knowledge which has perhaps faded, while drawing their attention to new developments in diagnosis. De Quervain adheres throughout to the plan of starting with the symptoms which caused the patient to seek medical advice and not to the method of deducing symptoms from an already made diagnosis; and, as he says, "if the appropriate questions have been correctly put, the problem will in every case be narrowed down more and more until, ultimately the student arrives at a definite diagnosis, either as the result of positive symptoms or by a process of gradual exclusion."

The book is divided into seven parts, covering respectively the surgical diseases of the head, neck, thorax, abdominal and pelvic viscera, pelvis and spinal column, upper extremity, and lower extremity. Under each of these headings the various surgical conditions of importance occurring in that region are taken up, not as in the ordinary textbook on surgery, but by a process of discussing and ruling out one by one the various conditions that affect the region, while an abundance of most excellent illustrations form an important adjunct to the text.

This is a book that is not only almost invaluable to the student, but to the progressive general practitioner and to the surgical specialist as well, a most complete index allowing the latter to refer to any desired subject with the least possible expenditure of time. It is a book that we feel we cannot recommend too highly, for the wealth of de Quervain's experience is instantly at the service of the reader who may be struggling with an obscure case or is trying to fit himself to do more accurate diagnostic work.

LA MALARIA. Parassitologia—Patologia e Clinica—Epidemiologia—Profilassi e Importanza Sociale. Per Dott. VITTORIO ASCOLI, Professore di Patologia Medica all' Università di Pavia. Torino: Unione Tipografico-Editrice Torinese, 1915.

THE first half of this work is devoted to laboratory subjects—the parasites, the parasitism and the reaction to it of the organism, the anatomical and functional disorders, the action of quinine on the human organism and on the parasite.

The clinical chapters deal with the acute, pernicious, and chronic types, and the phenomena exhibited by the organs of the infected subjects *in vivo*. Next in order comes the epidemiology of the malarias, and since this is a function of mosquito transmission, the author retraces his steps from the clinic to the original domain of biology. In some respects it would seem more natural to have discussed the hematozöon and the mosquito in the same section of the book, but the latter is a work of reference and not a textbook, so that the arrangement is of minor importance. The eudimicity and prophylaxis follow, and the section on the social aspects of the disease completes the work.

The name Ascoli is well known in Italian medicine and science, and at least three of the name, including the author, are well-known pathologists. The book represents the most ambitious effort yet made to write an exhaustive monograph on malaria and the success is such as to disarm criticism. The book is honestly written, without padding, and the numerous references are genuine, *i.e.* each author quoted has been consulted. Years must have been required for the preparation of so complete a volume. The illustrations are not overdone.

SURGICAL NURSING IN WAR. By ELIZABETH R. BUNDY, M.D. Member of the Medical Staff, Woman's Hospital, Philadelphia. Formerly Adjunct Professor of and Demonstrator of Anatomy, Women's Medical College, Philadelphia, etc. Author of a Text Book of Anatomy and Physiology for Training Schools. With 37 illustrations. Price, 75 cents. Philadelphia, P. Blakiston's Son & Company, 1917.

NURSES are required in abundance at the front; in fact, they are almost if not quite as essential as surgeons. But an untrained nurse is of little or no use; indeed, she is often more of a bother. Sir Frederic Treves, speaking of the large number of society ladies who came out from England to South Africa during the Boer War to offer their services as nurses, said: "There are two nuisances in South Africa, flies and women, and of the two the women are the worse." It is time that a woman imbued with the best intentions who has had no experience of nursing should not be allowed to go to the front in this capacity. Dr. Bundy emphasizes this in the little book under review and describes the different kinds of injuries inflicted in modern warfare, infection, shell shock, hemorrhage, and so on, and the various methods of treatment, especially, of course, from the surgical nurse's point of view. The book is well put together and adequately illustrated, and may confidently be commended to the attention of nurses and would-be nurses.

ELECTRODIAGNOSTIC DE GUERRE. Par A. ZIMMERN et P. PÉROL. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1917.

THE name of Zimmern should be a guarantee of the excellence of this work. The apparatus required is of the simplest—a portable galvanic battery, an ordinary faradic coil, storage cells, and electrodes. The authors also describe the use of condenser discharges. The technique of exploration is practically the same as in civil practice. In the latter portion of the work the various war conditions are described which require electrodiagnosis—traumatic paralyses, spinal cord lesions, traumatic psychoneuroses, reflex paralyses and contractures, ischemic paralyses, toxi-infectious neuritides, etc. Since all of these conditions have their counterparts in civil practice, it is not so much the contents of the book as it is the need of a small manual for the use of medical men at the front which makes this small volume a necessity.

Society Reports.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Wednesday, November 28, 1917.

THE PRESIDENT, MAJOR HENRY D. JUMP, IN THE CHAIR.

Symposium: "The Function of Orthopedic Surgery in the War."

Activities of Orthopedic Surgery in the War.—Major DAVID SILVER in his presentation of this subject said that in the organization of orthopedic surgery the Surgeon General had been guided very largely by the experience of the English Army and had in addition paid special reference to the following points: (1) The securing of a sufficient personnel; (2) Provision for an ample number of beds; (3) The reception of the wounded soldier as early as possible in the division to which he belonged, and with the least possible change of dressing. The securing of the personnel, he observed, had progressed very satisfactorily, as there were now about 85 men in training in Europe, 60 men assigned to camps in this country, and 80 or more placed in courses of instruction, with a considerable number still unassigned. Especial attention had been paid to the training of men lacking an adequate fundamental knowledge of orthopedic surgery. For these men the plan of instruction consisted of intensive courses of six weeks' duration, work in the cantonment hospitals under qualified orthopedic surgeons, and later work abroad as assistants to qualified men. Efforts were also being made to instruct medical men generally, the line officers, and the enlisted men themselves in the care of the feet, the handling of minor joint injuries, and the simpler injuries of the back. In the plan for the organization of the work in France Major Silver stated that the Surgeon General had arranged for the establishment of an orthopedic section in each hospital. This would be placed beside the fracture section in order that the same brace shop and curative workshops might be used for both. From 5 to 7½ per cent. of the wounded were expected to be returned to this country; these would be placed in the general reconstruction hospitals now being planned in the various sections of the country. Here the reeducation work would be carried out. The Surgeon General had established a laboratory for the study of the various problems connected with artificial limbs. While it was thought there would be little difficulty in supplying artificial legs to the soldiers, which production had reached a high degree of perfection in the hands of the American manufacturer, the question of the substitute arm presented more difficulties because of the complicated demands made upon it in the attempt to supply the functions performed by the normal hand. So far it has been found more satisfactory to use some form of mechanical hook for labor, reserving the hand for social use. Orthopedic surgery was concerned also with the industrial problem which was equally important to that of the military. The comparison of statistics in his opinion clearly demonstrated the great importance of applying to industrial work the same plan which had proved so valuable in military work. The economic loss of industrial accidents, he believed, ultimately assumed an importance equal to that of the casualties of war. In view of the industrial struggle likely to follow the termination of the war Major Silver believed it of vital importance that the reeducation plan should embrace both the military and the industrial need.

The Civic Aspects of Orthopedic Surgery in the War.—Major HENRY R. HAYES recalled that during the European struggle prior to America's entry into the war that which impressed the country above all else was the frightful loss in the unearned increment of the young men of the nations involved. To alleviate such a condition the United States Government had said to those returned, disabled in service: "We will restore or reconstruct you physically and mentally so far as possible. We will still further reeducate you if you cannot be returned to service, that you may earn a living which will be in addition to the compensation which you will regularly receive from the Government for the injuries incurred in service. All this will be done for you while in the Army." While casually the problem might not seem to be one of large proportions, analysis would not bear out this opinion; the man returned disabled would probably need in addition to the surgical treatment received overseas, further surgical and curative treatment at home. His medical and mental limitations with relation to the character of his previous occupation in civil life must be carefully studied by the medical and vocational board to determine the specific training he should have. England and France had made great advance in surgical and civic reconstruction. It was the function of surgeons and physicians to state what men with given disabilities could not do. Experts in vocational training must advise what trades should be taught the disabled. Employers and employees must advise upon the local trade and labor markets. There must be fundamental organizations that employers and employees might not be asked to take unreasonable risks; neither should there be discrimination against the cripple. A man reconstructed and reeducated must be presented to society, equipped to earn the pay of a given job. Reference was made to the fact that in the State Compensation Act one of the difficult problems yet to be settled was that of the extra liability involved in the employment of a disabled soldier. It would seem unreasonable to ask the employer to assume this liability. Another question to be studied was that of the requirements of organized labor with relation to the closed shop and its bearing upon the reeducation and employment of the disabled soldiers. Exemptions under the National Army Draft Law had been astonishingly large and not a small number of such disabilities were orthopedic in character. This situation was being studied by one department of the Government that such disabilities in younger and future generations might be minimized. Reconstruction work would require the close cooperation of Army Federal Bureaus, State and local officials, and civilian organizations. Industrial surgery, he believed, was destined to make rapid progress. Yearly there had been more industrial injuries in this country than there probably would be in the war. The hope was expressed that the experience acquired by orthopedic surgeons in the war might be adapted to industrial and civic reconstruction that there might be a more sound body politic, and the "passing of the cripple."

Dr. G. G. DAVIS, member of the Orthopedic Advisory Council, remarked upon the apparent necessity of the occurrence of a great war to arouse the people to a sense of their responsibility. Recognizing the importance of the military and industrial reconstruction, Dr. Davis felt that the purely civil cripple was not yet receiving the attention to which he was entitled. Too few institutions were maintained for reconstructive work alone. For general surgical work there was ample provision, but a standing rule in such hospitals was that the patient treated for injury should not remain more than three months. While some cripples could be cured within this time, many could not, and as a result throughout the community there was a class of cripples evidencing this lack of provision for their proper care. His own work gave ample illustration of this fact; for example, a man treated in a general hospital for an injured elbow might be discharged with the wound healed but with a crippled arm. Such a man would appear in the community as a cripple until he came under treatment for the restoration of his arm to a working condition. Another example might be seen in the instance of a child with a tuberculous condition of the hip; although the condition cleared up, a deformed hip was the result, necessitating admission to a hospital where the crippled condition might be remedied. Dr. Davis expressed the belief that nearly all cripples of a community could by proper treatment and education be made largely self-supporting, and many entirely so. While this problem had always occupied the attention of the orthopedic surgeon the war had emphasized its importance to the people generally. He cited the fact that in the Widener Home for Crippled Children with which he was connected nearly all children going out from the home were occupying good positions. He decried the prevailing tendency of ignoring or absolutely refusing the cripple the chance to work even though he was qualified. While employers ought not to be asked to assume the added liability involved in the employment of the maimed in some of the industries, he be-

lieved there should be some adjustment of this factor not yet provided for in the Workman's Compensation Act. Dr. Davis expressed his hopeful opinion, however, that the interest and efforts of the community would be directed with more earnestness than in the past to the reconstruction work for the purely civil, as well as for the military and the industrial cripple.

Dr. A. BRUCE GILL, referring to the statement that experts must advise upon the matter of trades to be taught the disabled, observed that such experts would of necessity be hard to secure, since the work discussed was in its very beginning. No evil, he said, was unmixed, and the opportunity for the cripple from this time would be such as it never had been before. There were at present but two comparatively small institutions in the State devoted to the training of cripples for the industrial world, and but four States in the Union giving any State attention to the work. He emphasized the need for cooperation and study to equip, and to find industrial positions for, the cripples returned to us after the war. Already the war had shown employers that the cripple was capable of doing work heretofore refused him.

Dr. CHARLES K. MILLS, in referring to the special courses of training for military men given in the city, regretted that more thorough coordination had not been observed in organizing the groups, there being, for example, a neuropsychiatric, a neurosurgical, and an orthopedic group. The relations of orthopedic surgery to neurology he emphasized as of the highest importance. The first consideration in the treatment of cripples should be the diagnostic study. The surgeon should have a knowledge of the various conditions of the nervous and muscular systems, the bones, and joints involved in disabilities. In the training of men for orthopedic work a very considerable degree of study should be devoted to neural medicine. Many cases cited in the present war reminded him of the statements of Sir Benjamin Brodie and Sir James Paget that functional hysteria was not due to organic injury of nerve, muscle, bone, or tendon, but to certain special conditions of the nervous system. Dr. Mills very strongly emphasized the importance of diagnosis founded upon a study of the nervous system as well as of the visible injury. Every orthopedic base hospital or reconstruction hospital should have a neurological member on its staff. He cited the Orthopedic Hospital and Infirmary for Nervous Diseases as an instance of the advantage of combining surgical with neurological work. This great hospital with these coordinated branches brought about by the great neurologist, S. Weir Mitchell, with Dr. Thomas G. Morton as surgeon and honored officer, had accomplished a class of work not otherwise possible than upon these lines.

Major SILVER, in closing, called attention to the fact that orthopedic and reconstruction were not synonymous terms, and agreed with Dr. Davis upon the urgent need of provision for orthopedic work in general hospitals. The lack of such provision presented one of the most important industrial problems. The missing link, for instance, of a man's discharge from a hospital and his acquisition of atrophy from a disused injured member, must be supplied. While the question of experts mentioned by Dr. Gill involved difficulty, yet any who had seen what could be done by amputated men would not ask for more finished experts; one such example was that of a man who had one arm amputated and who was now practising dentistry. In the reeducation of the crippled soldiers he felt that those essaying to give the instruction would be rather the ones who would be reeducated.

War Activities in the Surgeon General's Office.—Major JOHN D. MCLEAN delivered an address with this title. Emphasis was placed upon the advance in preparedness in the medical department of the army, due to the fact that the doctors had volunteered. Of 18,170 commissions recommended to be issued to physicians, 14,862 had been accepted. Many men had asked for immediate service. While a request for a particular service would carry weight it did not insure its receipt. Men were being classified according to the work they were qualified to do. It was urged that every doctor physically, mentally, and morally qualified join the M. O. R. C., that they might be so qualified, even though they were not called for active duty. While all were wishing that the war might be over, Major McLean quoted Major Crile in saying that the French thought that the war may be "half over." A surprisingly large number of doctors, Major McLean said, were in the Naval Medical Review Corps. The dental profession was also largely represented here. Reference was made to the organization of a unit of medical men who but for age or disability would be in the M. O. R. C., whose function would be to work in association with the Red Cross, one feature of which work would probably be "civilian relief" in the matter of medical attention to the families of sailors and soldiers. The selection of soldiers for the next army formed another problem of the surgeon general's office, it having been realized that the medical examination of the first army was not 100 per cent. efficient. In the solution of this problem the creation of an advisory medical board had been planned. It had been suggested that a member of the M. O. R. C. should be appointed in each State by the President, whose duty it should be to aid the Governor of the State in the formation of medical advisory boards in connection with the medical selective service law. For the guidance of the young doctor between 21 and 31 called into camp without having applied for a commission, Major McLean advised that he at once make application for a commission. Another problem instanced was that of the young physician who possibly had been rejected by the M. O. R. C. examination but accepted by the local board. Such a man, if accepted by the camp surgeon, should apply for a commission. In such instances the surgeon general's office had been extremely lenient and a commission in such case would probably be issued.

Major CHARLES A. E. CODMAN spoke upon the work of the Pennsylvania State Committee of the Council of National Defense, medical section, one phase of which work was not only the taking of a census of the physicians of the State, but also the gathering of statistics upon their special line of work. The work done in Pennsylvania was being duplicated in every State of the Union. Major Codman claimed a justifiable pride on the part of the medical profession of the State that Pennsylvania stood at the head of the list in medical preparedness which position was due to the volunteer work of its individual members.

Albuminuria, causation and curability of, 170.

Alcohol and fatigue, 383; and therapeutics, 666; drain in septic cases requiring cesarean section, 702; in breast milk, 968; intranervous injections of, in the treatment of causalgia, 784; problem, outlines of new work concerning the, 418; relation of industrial unrest to, 377; remedies in acute septic diseases, 778; synthetic, 425.

Alcoholism in Grand Canary Island, 162; in relation to epileptoid states and epilepsy, 100.

Alienists, why they laugh at, 463.

Alimentation of Italian soldiers, 873.

Alopecia, treatment of, 750; areata, treatment of, 968.

Alvarenga prize, 691.

Amaurotic family idiocy or infantile degeneration with symmetrical bilateral blindness, 1074.

Ambrine, the use of, with special reference to severe burns, 556.

Amebic dysentery, carriers of, among cases of irritable heart, detection and treatment with emetine bismuth iodide, 1089.

American ambulance ceases to exist, 380.

American Association of Electrotherapeutics and Radiology, 778.

American Medico-Psychological Association, an early meeting of, 47.

American University Club in Paris, an open, 378.

Amnesia, attempts at cure of, by means of free association and hypnosis, 345.

Amputation, flapless, a method of, with subcutaneous division of the bone at a higher level, 558; methods of, influenced by modern artificial limbs, 956.

Analysis, chemical, of the blood as an index to treatment, 1094.

Anaphylactic reactions to normal sera, 870.

Anaphylaxis and immunity, cellular and humoral factors in, 431.

Anatomy, comparative, of musculus palmaris brevis, studies in, 958.

Anders, J. M., treatment of chronic Bright's disease, 311.

Anemia and oral sepsis, 1095; pernicious, 721; pernicious, treatment of, by transfusion and splenectomy, 1042; secondary, in infants, treatment of by blood transfusion, 437.

Anesthesia, ether-oil, by rectum, 956; in obstetrics, 902.

Anesthetic, a new local (nikalgin), 555.

Anesthetics, administration of, at the front, 459; administration of, not practice of medicine, 243; in war hospitals, 1119; local, for minor operations, 693.

Aneurysm and indirect trauma in arteries of base of brain, 1090.

Angina, Vincent's, among the troops in France, 1120.

Ankle, ligaments of, importance of, in correction of congenital clubfoot, 648.

Ankylosis, fibrous, radium in the treatment of, 160.

Anomalies, osseous, 643.

Antenatal pathology, 82.

Anthrax traced to China, 378.

Antiphones, 513.

Antisepsis, iodized hydride, a half century ago, 1075.

Antiseptics, method of applying, to deeper parts of wounds, 606.

Antisyphilitic, a new, 906.

Antitoxin for gas bacillus infection, 859, 870.

Anus, cancer of, treatment of, 887.

Aorta, abdominal, complete thrombosis of, 19; localization of syphilis in, 173; rupture of the, rare case of, 473; syphilis of, 1095.

Aortic insufficiency, arterial tension in, 650; insufficiency, left and right diastolic murmurs in, 518.

"Apaches," a psychologist on the, 775.

Aphasia, and hemiplegia caused by subdural hemorrhage, osteoplastic flap, recovery, 741.

Apoplexy, professional, 950.

Appendicitis, causes of, 557; complicating early ectopic pregnancy, 1008; familial, and hereditary syphilis, 344; in nine months' old baby with autopsy record, 436; local anesthesia in sixty cases of acute and chronic, 481; post-operative, in stump, 614.

Appendicular abscess, treatment of, 701.

Appendix, intussusception of the, 741.

Argyria, 948; caused by organic silver preparations, 166.

Army camps, terrible conditions at, 1122; National, and National Guard, health conditions in, 1035; camps, pneumonia and measles in, 990; cantonment at Camp Upton, psychiatric experiences at, 877; dental controversy, 908; medical corps, appeal for volunteers for, 111, 289, 337, 463; Medical Museum, library of, 1023; Medical Museum, moving pictures for, 1035; medical museums, 663; Orthopedic Board, 333; sanitary corps for, 67; surgeons for Roumania, 991; venereal diseases in, 596.

Arrhythmia, report of three cases of, 441

Arterial tension in aortic insufficiency, 650.

Arteries, base of brain of, indirect trauma and aneurysm of, 1090.

Arteriosclerosis, new conception of, 954.

Arthritis and oral sepsis, 1095; deformans, is it infectious? 775; deformans, treatment for, 926; infectious, 14.

Arthritism, what is it? 913.

Artificial limbs, modern, influence upon methods of amputation, 956.

Ascites, autoserotherapy of, 168.

Association of Military Surgeons, 686.

Asthma, bronchial, 190; bronchial, etiology and treatment of, 382; bronchial, modern conception of, 815; traumatic, 1783; treatment of, 134; treatment of, by pituitrin and epinephrin, 10.

Astragalectomy, bilateral, and tendon transplantation for paralytic club foot, 614.

Asystolia, the limits of, 824.

Auscultatory sphygmomanometry, 1045.

Autografts, homo and, in the regeneration of a divided nerve, 1133.

Automatism and loss of consciousness in inebriety, 1026.

Autoserum treatment for chorea, 414.
Avellis, syndrome of, 20.
Aviator, examination of an, 724.
Axilla, carcinoma, metastatic, following cancer of parotid gland, 614.

B

Babies, scientific, 750.
Baby killing, 866.
Bacilli, colon, focal lesions produced in the rabbit by, isolated from pyelitis cases, 392.
Backache, lumbrosacral, in women, 1049.
Bacteriology at the front, 167; influenzal and pneumococcal, in purulent bronchitis, 644; and war, 900.
Bailey, P. Sanford, osmosis, a factor in the treatment of tuberculosis, 55; osmosis, an immunizing factor in tuberculosis, 617.

Carter, W., gas bacillus infection in a chronic mastoiditis with cholesteatoma, 104.
Casualty clearing station, 332; treatment of wounds by a solution of soap in the, 1120.

Catarrh, acute nasal, treatment of, 222; nasal, chronic, treatment of, 1056.
Catarrhal conjunctivitis, acute and chronic, treatment of, 1056; deafness and other mucous membrane and systemic conditions, treatment of, hot air and calomel vapors in, 593.
Causalgia (thermalgia), 472.
Causes of disease, Bradshaw lecture on, 1044.
Cephalalgia, lumbar puncture in the treatment of certain forms of essential, 434.
Cerebrospinal fever, premeningitic rash of, 343; fluid, mastic, reaction on, 675; meningitis, see Meningitis, cerebrospinal.
Cervix, carcinoma in, following suprapubic hysterectomy, 656; carcinoma of, recurrences of, after five-year period, 656.
Cesarean section, alcohol drain in septic cases requiring, 702; for eclampsia in twin pregnancy, 941; in selected cases, a plea for more, 856; pre-eclampsia, 701.
Chemistry, premedical training in, 1038.
Chemotherapy of lupus, 1132.
Chest, gunshot injuries of, with special reference to hemothorax, 433.
Chilblains, treatment for, 880.
Child, carcinoma, primary, of the liver in, 387; diabetes insipidus in, 487; emotional life of, 610; growth, control of, by photoauthropometry, 1002; indicanuria in, 439; luetic nephritis in, 439; marasmic, influence of maternal oral sepsis on, 33; pulmonary tuberculosis in, of school age, diagnosis of, 406.
Childbirth, see Parturition.
Childhood, rheumatic fever in, some observations on, 1097.
Children, care of sick, in the home, 348; dependent, the care of the city's, 348; heart disease in, 1124; hypoplastic and mentally impaired, treatment of, 1015; nervous states and nervous attacks in, 129; skin diseases, *x*-ray and radium in treatment of, 875.
Children's, diseases, civilization and, 137; Hospital and School of New York City, reorganization of, 1070.
China, menace of morphine to, 76.
Chlorine gas, treatment of scabies by, 384.
Chloroform, in labor, study of use of, 703.
Cholecystectomy versus cholecystostomy in gallstones, 598.
Cholecystostomy, cloudy English and, 756.
Cholelithiasis, *x*-ray examination in, value of the, 511.
Cholera, anti-vaccination, 1045.
Cholesterin in pleural exudate, 824.
Chorea, autoserum treatment for, 414.
Chorial epithelia, proliferation of, excessive in case of repeated tubal pregnancy, 958.
Chorioepithelioma following a hydatid mole, 522.
Christopher, F., a differential history form for enlargements of the thyroid gland, 985.
Cigarette smoking, soldier's heart and, 770.
Circulatory inefficiency, observations on, 1000.
Circulation, cardiopulmonary, study, 1131.
Circumcision, bloodless, cosmetically perfect, 680.
Civilization and children's diseases, 137; and diseases of adult life, 138; and diseases of middle life 140; effects of, on the morbidity and mortality of tuberculosis, 94.
Clark, L. Pierce, the results of the psychic treatment of mental torticollis, 48.
Cleft palate and harelip, operations for, 679.
Clinic for treatment of syphilis, 1040; free dental, 950; free, for speech defects, 597.
Clinical Association of American Peroral Endoscopists, organization of, in Philadelphia, 1040.
Clubfoot as a product of evolution, 62; congenital, importance of ligaments of ankle in correction of, 648; paralytic treatment of, by bilateral astragalectomy and tendon transplantation for, 614.
Codex of effort, 650.
Cold upon the body, investigation into the effects of, report upon, 911.
Colectomy, avoidance of, 75.
College, normal, the, as a factor in the dissemination of public health knowledge in the South, 1094.
Colloid complexes and their importance in biology, pathology, etc., 560.
Colon, idiopathic dilation of the, skiagraph of a case of, 393.
Colony treatment and after-care, experiences in, 1130.
Columbia Base Hospital opened for army, 639.
Commotion psychosis, 1090.
Community work, intensive, in Tennessee, 1093.
Complement fixation test in tuberculosis, clinical value of, 1054.
Complex, complex, the, 1125.
Congenital giant, growth of the extremities, 1132.
Conjunctivitis, catarrhal, acute and chronic, treatment of, 1056.
Consciousness, loss of, and automatism in inebriety, 1026.
Conscription unnecessary, 337.
Constipation in soldiers, 77.
Consumption. see Tuberculosis, pulmonary.
Consumptives, compromising with, 447.
Contractive, functional, treatment of, by fatigue, 729.
Cornell, W. B., the reorganization of the New York City Children's Hospital and School, 1070.
Correspondence: Canadian, 734, 1085; London, 31, 74, 116, 254, 293, 379, 429, 554, 602, 692, 733, 869, 907, 952; Paris, 64, 207, 254, 341, 380, 429, 555, 602, 693, 779, 819, 869, 908, 953, 997, 1129.
County Medical Society of New York, resolutions before, 951.
Convalescent malarial soldiers and farm labor, 548.
Convulsions, protein disorders and, 763.
Cooperation between physician and surgeon, 111.
Coopernail, G. P., a plea for more cesarean sections in selected cases; 34 consecutive cases without mortality to mother or child, 856.
Copper and potassium cyanide, treatment of tuberculosis with, 575.
Cornea, opaque, reestablishment of transparency of, 29.
Cornwall, E. E., practical points in the use of strophanthus, 451.
Coroner's inquest, authority for, 154.
Corpus callosum, tumor of, 742.
Court plaster, germs in, further investigation of, 467.
Craniocerebral traumatisms, temperature as guide to diagnosis, prognosis, and surgical treatment in, 736.
Cretinism, sporadic, 293.
Crippled, fitting the, for agriculture, 66; soldier, rehabilitation of the, 510.
Cripples, employment of, 1122; reeducation of war, 554.
Crothers, T. D., loss of consciousness and automatism in inebriety, 1026; outline of new work concerning the alcoholic problem, 418; a possible physical basis for inebriety, 468.
Cunningham, W. C., neurotization of paralyzed muscles by inplantation of motor nerves, 223.
Cutireaction after tuberculin inoculation, significance of the, for the therapy and prophylaxis of tuberculosis, 474.
Cystitis, acute, 176.
Cystoma, serous ovarian, histogenesis of, 1046.
Cysts and fistulas of Bochdalek's duct, 1123.
Cytologic formula of serous effusions in the tuberculous, 345.

D

Davin, J. P., proposed registration for all patients taking opium, 907.
Deafness, catarrhal, treatment of, hot air and calomel vapors in, 593; from corticocerebellar commotion, 421; progressive, from chronic secretory otitis media, treatment of, 820.
Death, ocular reactions in, diagnosis of, 689.
Death rate in Rio de Janeiro, 574.
Death, sudden and silent peritonitis, 345.
Decubitus, management of, a system in use at Kings County Hospital, 622.
Deficiency, mental and pauperism, 1123.
Degenerative changes occurring in bichloride poisoning, 642.
Dehydration of blood and organs in diabetic coma, 35.
De Lee stethescope, use of, 1009.
Delinquents, juvenile, physical status of, 1094; study of, 1004.
Dementia precox, endocrine organs of, 987; focality of microscopic brain lesions in, 175.
Dental clinic, free, 950.
Dentition, disorders of, treatment of, 1056.
Dermatitis due to explosives used in air raids, 433.
Dermatology, metabolism and immunity in, problems of, 518.
Diabetes, cure of, fasting, 644; dehydration of blood and organs in, coma of, 35; insipidus, bibliography of, 492; insipidus in children, 487; insipidus, influence of pituitrin on, 171; mellitus, acute, 987; mellitus, following mumps, with pulmonary tuberculosis, 384; treatment of, static wave current as an aid in, 832.
Diabetic polyneuritis, 823.
Diarrheas, acute, in infancy, classification and treatment of the, 1096.
Diet, importance of, as a factor in the production of pathological changes, 432; laws, primitive, 1111; potash poor, effects of, 958.
Dietetics, report on, 831.
Digitalis and digitoxin, on blood pressures in man, influence of large doses of, 605; in auricular fibrillation, 441.
Dilation of the colon, idiopathic, skiagraph of a case of, 393.
Diphtheria carriers, treatment of, 77; control of, 32; laryngeal, intubation in, 1068.
Diphtheritic wound infection among returned soldiers, report of an outbreak of, 517.
Dislocation and fracture of sacrum, 741.
Dispensary treatment of tuberculosis, regulation of, 1041.
Diverticulum, pulsion, of the esophagus, physical signs of a cavity in, 824.
Dogs, mobilized, of the French sanitary service, 549.
Doty, Alvah H., poliomyelitis, 135.
Dover, H., on the use of small doses of pituitrin for inducing and shortening labor at term, 238.
Dowman, C. E., emergency head surgery, 760.

Leucocytes in irritable heart, 199.
Leucoplakia buccalis, new mode of treating, 465.
Leucorrhea, complement fixation reaction as applied, a new, 821.
Leukemia, myeloid, with bilateral growths in orbit causing exophthalmus; myeloid, with bilateral growths of motor nervous system, 1046.
Library of the Army Medical Museum, 1022.
Lich, C. W., rationale, indications, and contraindications of the Nauheim bath, 268.
Life, origin and nature of, 1006.
Lightfoot, E. N., instruments of precision for the Percy treatment of uterine and other cancer, 151.
Liver, tropical abscess of, treatment of, 1048.
Liviereto's sign in myocordial insufficiency, 689.
Loewi test, of pancreatic insufficiency, 31.
Lopez-Silvero, J. E., report of two cases of multiple keloids, 673.
Lord Roberts Workshops, London, 554.

Lott, Y. C., observations and technique of lumbar puncture in seven hundred cases, 717.
Lumbar puncture in essential cephalalgia, 434; puncture, observations and technique of, 717.
Lupus, chemotheraphy, 1132.
Luttinger, P., research work interrupted, 429.
Lymphocytosis; a clinical study from group diagnosis, 954.

M

McCaskey, Donald, balancing body metabolism, and the quartz ultra-violet light, 633.
McCready, E. Bosworth, the treatment of hypoplastic and mentally impaired children, 1015.
McGaffin, C. G., a case of bothriocephalus infection, 327.
McGahey, R. G., points on nitrous oxide, 769.
McWilliams, C. A., memorandum on the technique of the suture of war wounds, 944.
Magnesium sulphate, tetanus treated by subarachnoid injections of, 1050.
Malaria, blood, new symptom in, 464; genesis of, 339; hyperdermic treatment of, 528; in children, treatment of, 616; infants, mammatis in, 608; microscopical histology of, 432; southern treatment of, 528; tartar emetic and, 645; treatment of, 616; Wassermann reaction in, 1131.
Male fern, poisoning by, symptomatology of, 1124.
Malignancy of biliary apparatus, 933
Malingering, 339.
Malpractice case, examination of medical experts and defendants in, 898.
Mannheimer, W. A., necessity of further administrative control of scalp diseases in children and adults, 587.
Marbled nails, prognostic and symptomatic value of, 1039.
Marcus, J. H., some ancient health laws of the Jews, 503; primitive dietary laws, 1111.
Massey, G. B., a new test for incipient cancer of the breast, 803.
Mastoiditis, chronic, gas bacillus infection in, 104; erysipelas as complication of, 382.
Mastoid operation in acute otitis media, 558.
Mattison, F. C. E., some of the newer methods of treating wounds, 937.
Mayo foundation becomes property of University of Minnesota, 513.
Mayo, W. J., the relation of the spleen to certain obscure clinical phenomena, 706.
Measles, control of, 32; in army, 901; in army camps, 990; laryngeal stenosis as a complication of, 1130; prevention of, 28.
Mechanical vibration therapy, 832.
Medical and surgical notes from Mesopotamia, 344; colleges form merger, 996; Congress, Spanish, of 1918, 574; examinations, 952; experience in southeastern Europe, 350; experiences in the Balkans, 351; experts and defendants in malpractice case, 898; famine, threatening, 375; inspection of schools in North Carolina, 1093; incompetents to be weeded out, 1122; negligence, alleged, court action in, 996; organization of police department of New York City, 562; officers training camps, 828; profession, duty of the, in time of war, 463; relations between Latin-America and France, 872; Reserve Corps, application for appointment (blank form), 335; Reserve Corps, letters from an M. M. R. C., 331, 371, 420, 468, 507, 546; service, casualties in, 21; Society of County of New York, election of officers, 996; students and hospital internes, drafting of, 338; students and hospital internes, drafting, protest against, 333; study, new, in speech correction, 1087; units, United States, attached to French and British forces, 861.
Medication, sublingual, 1117.
Medicine, illegal practice of, 457; and the moon: beliefs of other days, 1030; military, lectures in, 946; patent, use of, in practice without license, 1076.
Meltzer, S. J., history and analysis of methods of resuscitation, 1; how to employ the pharyngeal insufflation apparatus in cases of emergency, 164.
Meningitis, cerebrospinal, abortive, 513; cerebrospinal and mobilization, 197; cerebrospinal, premeningitis rash of, 343; cerebrospinal, simulation of, by neosalvarsan poisoning, 824; serosa, 1132; epidemic cerebrospinal, 165; influenzal, 345; meningococcus, a case of, in the newborn, with interesting and unusual features, 436; pneumococcal, 872.
Meningococci, pseudo, 733.
Meningococcus of Weichselbaum, 738; types of, 733.
Menstruation, precocious, 392; return of, in old age, 600.
Mental deficiency and pauperism, 1123; diseases and war, 637; disorders, 786; labor, curve of, 560.
Mentally impaired children, treatment of, 1015.
Mercury, action of, on syphilis, 1133.
Mesenteric vessels, embolism and thrombosis of, 1090.
Mesoaortitis with aortic insufficiency of luetic origin, 560.
Metabolism, balancing body, and the quartz ultra-violet light, 633; effect upon, of induced sinuous impulses, 833; in dermatology, problems of, 318; of normal infants, twenty-four hour, with special reference to total energy requirements, 388.
Metal protection for the soldier's heart, 1077.
Microphone as an aid in removing fragments of needles from the tissues, 774.
Middle life, diseases of, and civilization, 140.
Military, hygiene, German fighting forces, decrease in disease among, 337; Medical Association, Senior, 513; medicine, lectures in, 946; service, chronic enteric syndromes and, 913; service and the civilian practitioner, 351; statistics, 786; surgery and the specialities, 915.
Milk, albumin, in treatment of diseases of nutrition in nurslings, 1132; bacteria which proliferate before, and those which survive pasteurization, 409; commission, report of, 1053; food value of, 205; and health of children, 425; breast, alcohol in, 968; grading of, ten years' experience in, 999; intoxication, 994; production, human, effect of diet containing protein on, 438; sterilization of, electrical, 600.
Millstone, H. J., a cosmetically perfect, bloodless circumcision, 680.
Mind, probing the, 927.
Mitral stenosis, functional, 69.
Mobilization and meningitis, cerebrospinal, 197.
Moffett, R. D., the antoserum treatment for chorea, 414; and Greenberger, M., diabetes insipidus in children, 487.
Mole, chorioepithelioma following a hydatid, 522.
Molokai leper settlement, 629.
Montgomery, D. W., some disfiguring affections of the eyelids, 416.
Morphinomania and nephritis, 791.
Morris, M. Ford, Jr., bronchial asthma, 190; hyperthyroidism, 895; the treatment of lobar pneumonia, 589.
Mortality and occupation, 26; maternal, from childbirth in the United States and its relation to parental care, 525.
Moseley, E. L., milk sickness and tremblés caused by resin of white snakeroot, 428.
Moses, M. M., a mixed type of nephritis, 61; an intrathoracic thyroid tumor, 1025.
Moss, L. H., instruments of precision for the Percy treatment of uterine and other cancer, 151.
Moss as surgical dressing, 773.
Mothers, conservation of, 202.
Mouth infections, diagnosis and treatment of, 1095; menace of, 781; sepsis and arthritis, 1095; sepsis and the anemias, 1095; sepsis and the cardiovascular system, 1095; sepsis, material influence of, on fetus and marasmic children, 33; sepsis, relation of, to the nervous system, 1096.
Moving pictures for the Army Medical Museum, 1035.
Moynihan, Sir B., British Army Medical Corps, 827.
Mumps, diabetes mellitus following, with pulmonary tuberculosis, 384.
Munition workers, health of, 28.
Murmurs, diastolic, left and right, in aortic insufficiency, 518.
Muscle, gas gangrene, spread of, into, 34.
Myalgia, treatment of, 750.
Myocardial change, a possible electrocardiographic sign of, 472.
Myoma laparotomies, series of, 221, 697.

N

Nails, marbled, prognostic and symptomatic value of, 1039.
Nasal catarrh, chronic, treatment of, 1056.
Nasopharyngeal surgery, 864.
National Board of Medical Examiners, 996; Dental Association, 778.
Navy, medical transport of, arrangements of, 23.
Needles, the microphone as an aid in removing fragments of, from the tissues, 774.
Negligence case, failure to remove sponge from incision, 898.
Neosalvarsan, in treatment of tabes dorsalis according to Leredde's method, 1133.
Nephritis, acute, due to the *spirochæta hæmmorrhagica*, 1083; chronic parenchymatous edema of, 948; chronic, treatment of, 311; luetic, in infancy and childhood, 439; mixed type of, 61; trench, its later stages and treatment, 558; war, contribution to study of, 383.
Nephrosis, intermittent hydronephrosis and pyonephrosis in the female, 1050.
Neoplasms, see tumors.
Nerves, divided, homo and autografts in the regeneration of, 1133; optic, rhinogenic affections of, 739; peripheral, gunshot wounds of, 683; peripheral, gunshot wounds of, treatment of, 685; peripheral, injuries of, 1000; peripheral, treatment of, 1000; sedative for, 1102.
Nervous exhaustion, treatment of, 134; system, involuntary importance of, 68; system, motor bilateral growths of, with myeloid leucemia, 1046; system, relation of oral sepsis to the, 1096.
Neuralgia, formula for relief of, 880; treatment of, 222.
Neurasthenia in soldiers of home forces, 372.
Neuritis, diagnosis of, a wrong, 833; rational management of various types of, 832; treatment of, with special reference to sciatica, 662.
Neurological surgery, field of, 711.
Neuroses, post-gonorrheal, 375; war, etiology and treatment of, 859.
Neurosis problem in the light of war neuroses, 651.
Newborn, hemorrhagic disease in, treated by direct transfusion, 392; meningococcus meningitis in the, with unusual features, 436; uric acid content of blood in, 390.
Newton, R. G., plea for greater exactness in diagnosis and treatment of tuberculosis, 580.
New York City Children's Hospital and School, reorganization of, 1070.
Nicotine, perfusion of heart with, 1088.
Nikalgin, a new local anesthetic, 555.
Nitrous oxide, points on, 769.
North Carolina, medical inspection of schools in, 1093.
Nose and throat diseases of childhood, clinical lecture on, 737.
Nurse, public health, relative value of the, in the solution of the tuberculosis problem, 1093.
Nursing, maternal, restoration of, after sixteen days of complete interruption of, 393; service in camp zones, 549; service, consolidated, 366.
Nutrition, diseases of, in nurslings and their treatment with albumin milk, 1132; lowered, in tuberculosis, treatment of, 833.

Syndrome, infundibular, in tumor of the third ventricle, 434, 1045.
Syphilis, action of mercury on, 1133; and cancer, 405; and pregnancy, 16; Bruck's serochemical test for, 400 cases compared with the Wassermann, 515; clinic for treatment of, 1040; hereditary, and familial appendicitis? 344; hereditary, ignored, 77; in joints, latent

manifestations of, 1049; is it or not? 960; luetic biopsy, 650; modern treatment of, 766; of central nervous system, prophylaxis in, 999; of nervous system, intraspinal injections in treatment of, 871; of heart and aorta, 1095; of stomach and intestines, 1095; of the Incas, espundia, blastomycosis and, 339; reinfection in, 911; the soldier, the courtesan and, 816; splenic reflexes of Abrams in, diagnosis and treatment of, 586.
Syphilitic origin of fissured tongue, 650.

T

Tabes dorsalis, treatment of, by neosalvarsan according to Leredde's method, 1133.
Tachycardia, effort test of, 958.
Tachyphylaxis in therapeutics, 1089.
Tar in skin conditions, employment of, 704.
Tartar emetic and malaria, 645.
Taste, smell and, an exhaustion phenomenon in areas of sense of, 1090.
Taylor, J. M., premature old age, 758.
Teeth, diagnostic, 342.
Temperature, as guide to diagnosis, prognosis, and surgical treatment in craniocerebral traumatisms, 736.
Tendon transplantation and bilateral astragalectomy for paralytic clubfoot, 614.
Tennessee, intonsive community work in, 1093.
Tetanophobia, 866.
Tetanus, cryptogenic, 1126; magnesium sulphate and antitetanic serum, subarachnoid injections of, 1050; postseric, 861; war, 820.
Tetany, calcium and magnesium in the blood in, 170.
Therapeutics and alcohol, 666; physical, in war, 833; surgical, progress in, 495; tachyphylaxis in, 1089.
Thermalgia (causalgia), 472.
Thermos bottles, suitable for keeping milk warm, 385.
Thigh, gunshot fractures of, early treatment of, 861.
Thom, B. P., syphilis and pregnancy, 16.
Thomas, H. O., a reconsideration of the principles and methods of, 472.
Thrombophlebitis, primary, of hepatic vein, 173.
Thrombosis, complete, of abdominal aorta, 19; embolism and, of mesenteric vessels, 1090.
Thymus, enlargement of, treated by x-ray, 391.
Thyroid deficiency, relation of chronic infection to, 1096; gland, enlargements of, a differential history form for, 985; gland in gynecology, 700; tumor, intrathoracic, 1025.
Thyroidectomy, partial; an operation for transplanting and anchoring the remaining lobes of the thyroid gland, 842.
Thyroidism, signs and treatment of, 961.
Time element in some physical processes, 456.
Tissues, respiration, supervital of, in fever, 608.
Tongue, fissured, syphilitic origin of, 650; tuberculous ulcer of, primary, 607.
Tonsillectomy, foundations of voice impairment resulting from, 471.
Tonsils and rheumatism, 364.
Torbett, J. W., infectious arthritis, 14
Torticollis, mental, results of psychic treatment of, 48.
Toxemia, intestinal, diagnosis and therapy of chronic, 402; of pregnancy of hepatic origin, treatment of, by transfusion, 1007; preeclamptic, indications for interference in, 702.
Trachoma and army recruits, 244; bodies, 519; clinical course and diagnosis of, 1043; in recruits, 201.
Transduodenal lavage, technique of, in office practice with or without oxygen insufflation, 499.
Transfusion of blood, 651; and splenectomy in treatment of pernicious anemia, 1042; treatment of secondary anemia in infants by, 437; treatment of severe toxemia of pregnancy of hepatic origin by, 1007.
Transplant, peritoneal, repair of perforated gastric ulcer with a free, 474.
Trapezius, myotonic reaction of the, in pleuropneumonia tuberculosis, 473.
Trauma, indirect, and aneurysm of arteries of base of brain, 1090.
Traumatic injuries in war, treatment of, value of physical measures for, 832; intrapericardial hemorrhage, 863.
Travell, W., electricity, then and now, 627.
Trembles and milk sickness caused by resin of white snakeroot, 428.
Trench fever, 155; foot, 380, 547; foot and allied conditions, treatment of, by passive hyperemia, 1075; foot, severe form of, 119; hand, 548; leg, German view of, 547; nephritis, later stages and treatment, 558.
Tubercle bacilli in breast milk of tuberculous women, occurrence of, 383.
Tuberculin, human and bovine, in tuberculous disease of bones and joints, von Pirquet reactions to, 822; inoculation, cutireaction after, significance of, 474.
Tuberculide, papulonecrotic, 10.
Tuberculosis, anatomical investigations into frequency of, 911; and the war, 350; chemotherapy of, 1132; complement fixation test in, clinical value of, 1054; cytologic formula of serous effusions in, 345; county hospitals for, mandatory in New York State, 427; diagnosis and treatment of, greater exactness in, 580; diagnosis of, early, 143; in cattle, 910; in cattle, danger to children from, 910; in evolution, Is there a closed type of? 784; in the French army, 810; in France, 70; internal secretions as related to, in civil and military practice, 470; lowered nutrition in, treatment of, 833; miliary, in old age, frequency, 784; morbidity and mortality of, effects of civilization on, 94; nasal insufflations in diagnosis, prognosis, and treatment of, 668; of bones and joints, von Pirquet reactions to tuberculin applied in, 822; of knee joint in adults, operative treatment of, 695; of tongue, primary ulcer of, 607; osmosis a factor in the treatment of, 55; osmosis, an immunizing factor in, 617; otorrhea, diagnosis of, 559; pleuropneumonia, the myotonic reaction of the trapezius, 473; problem in Rio de Janeiro, 697; propathies of, 35; problem, relative value of the public health nurse in the solution of the, 1093; pulmonary, and the Wassermann reaction, 678; pulmonary, in children of school age, diagnosis of, 406; pulmonary, in workmen of certain Finnish towns, 1046; pulmonary, psychical changes observed in, and its relation to insanity, 969; pulmonary, significance of negative sputum examinations in, 1072; regulation of dispensary treatment of, 1041; respiratory, and the war, 548; should certain patients with, work? 881; suspects in French army, 372; treatment of, by means of a bacillus-destroying compound, 847; treatment of, with copper and potassium cyanide, 575; vesical, ureteral, and renal, 742; warfare against, 739; what the American soldier in France should know about, 751.
Tuberculous recruits, standard for exemption of, from the National Army, 488.
Tulllidge, E. K., war and venereal diseases, 505.
Tumor, bladder, 1115; mixed cell, of kidney, in infant, 657; nervous system, motor of, with myeloid leucemia, 1046; of corpus callosum, 742; of the third ventricle, the infundibular syndrome in, 434, 1045; of urinary bladder, 1048; orbital leucemic, causing exophthalmus, 1046; pulmonary, artificial pneumothorax as a diagnostic measure in, 1133; thyroid, intrathoracic, 1025.
Tympanismus vagotonicus, 987.
Typhoid fever, agglutination tests for diagnosis of, in antityphoid inoculated individuals, 383; immunization infection and antityphoid vaccination, 519; intravenous injection of foreign protein and peptone, 424; osteoperiostitis, treatment of, by vaccinotherapy and surgical intervention, 696; prophylaxis, successful 642; roseola of, 1133; vaccine, triple, reactions produced by prophylactic inoculations with so-called, 879.
Typhus fever, etiology of, 1083.
Tyramine as an adjunct to morphine in labor, 568.

U

Ulcer, duodenal, diagnosis of, 126; duodenal, medical treatment of, 127; duodenal, stools in, blood in, 942; peptic, merits of medical and surgical treatment, 353; perforative gastric and duodenal, 1082; tropical phagedenic, in French - African troops, 639.
Ulceration, persistence of, 635.
Uneasiness, antecedent state of, as cause of certain normal and abnormal types of behavior, 1087.
Unconscious, Freud's psychology of the, 118.
University headquarters, new, 997.
Uranium nitrate, therapeutics of, 361; poisoning by, 174.
Uremia and internal secretions, 20.
Ureteral calculi, bilateral, 1020; calculi, multiple, 742.
Urethra, anterior, diagnosis and treatment of conditions of, through the urethroscope, 1057; posterior, lesions of, their symptomatology, diagnosis and treatment, 583.
Urethritis patient, some suggestions regarding the, 453.
Uric acid, elimination of, in gout, 170; endogenous, physiology of, 865.
Urethroscope in diagnosis and treatment of conditions of anterior urethra, 1057.
Urinary bladder, tumors of, 1048.
Urination in women, frequency of, etiology and treatment of, 696.
Urine, glucose content in, new method for determination of, 502; spirochetes, in, occurrences of, 782; of picric acid workers, 342.
Urticaria, treatment of, in children, 222.
Uterine hemorrhage, non-malignant, radium in, 1049.
Uterus, acute dilatation of, 656; cancer of, operation or irradiation for? 659; fibroids following parturition, a case of gangrene of; panhysterectomy, 703; hysterectomy, fundal, to reduce menstruating surface, 653; prolapse of, 654; ruptured, 1009.

V

Vaccination, anticholera, 1045.
Vaccine and serum, distribution of, by the State, 1093; tetanus germs in, 817; therapy for whooping cough, 704; therapy, fundamentals in, 1096; therapy, non-specific character of, 516; therapy, treatment of typhoid osteoperiostitis by, 696; triple typhoid, reactions produced by prophylactic inoculation with so-called, 879.
Vagitonia, paroxysmal, 20.
Vagotony, case of, 167.
Valve, ileocecal, incompetency of the, *vs.* Lane's kink, as cause of ileac stasis, 399.
Van Alstyne, E. V. N., non-specific protein treatment of psoriasis, 538.
Van Becelaere, J., the persistence of ulceration, 635.
Van Beuren, F. F., Jr., statement regarding the selective draft of physicians, 468.
Vanderveer, A., progress in surgical therapeusis, 495.
Vasodilatation, 87.
Venereal disease, 786; advertisements of remedies for, prohibited, 161; diseases, control of, in Rochester, 951; diseases in army, 596; diseases in the war, 64; diseases, prophylaxis in, legislation in, 687; diseases, prevention of in army, 200; diseases, war and, 505; prophylaxis, 781; prophylaxis, legislation in, 687.
Ventilation and cubic space for infants in institutions; a report, 910.
Version, with report of 150 cases since September, 1916, 702.
Vertigo, voltaic, in affections of internal ear, 696.
Vincent, W. G., malignancy of the biliary apparatus, 933.
Vincent's angina among the troops in France, 1120.
Vineberg, H. N., diagnosis and treatment of abortion, 177.

Visceroptotic, treatment of the, 468.
Visual acuity, professional, of the soldier, 900.
Vital economics, course in University of Rochester, 601.
Vitamines in infant feeding, 13; in soldiers' rations, 904.
Volunteering, mass, 962.
Vomiting of pregnancy, 897; of pregnancy, treatment of, 616.
Von Pirquet reactions to human and bovine tuberculin in tuberculous diseases of bones and joints, 822; test, value of, as controlled by autopsy findings, 438.
Von Unruh, V., results of treatment of tuberculosis by means of a bacillus-destroying compound, 847.

W

War, activities in office of surgeon general, 1136; amenorrhea, 1133; and bacteriology, 900; and crime, 333; and hospital internes, 902; and medicine, introductory remarks, 349; and tuberculosis, 350; and Pasteur Institute, 1129; Austro-Italian, sanitary statistics of, 945; bread and its effect on health, 907; conditions, skin diseases and their treatment under, 638; cripples, re-education of, 554; edema, 899; erysipelas, treatment of, 651; fatigue, 21; hospitals, anesthetics in, 1119; mental diseases and, 637; nephritis, study of, 383; neuroses, etiology and treatment of, 859; neuroses, neurosis problem in the light of, 651; orphans, 953; orthopedic surgery in, activities of, 1135; radiography, 637; respiratory tuberculosis and the, 548; surgery, 683; surgery, abdominal defense in, 594; surgery of the spinal cord, 918; tetanus, 820; wounds, orthopedic prophylaxis in, 1132; wounds, technique of suture of, 944; wounds, treatment of, with flavine, 989.
Washington, George, last illness of, 1128.
Wassermann in certain syphilities, failure of the, 873; reaction, 692; reaction and pulmonary tuberculosis, 678; reaction in malaria, 1131; reaction, methods of performing the, comparative study of, 557; reaction, uniformity in the, report of committee on the, 1094; test, Bruck's serochemical test for syphilis; a report of 400 cases compared with the, 515; tests, error in, causes of, and how to avoid them, 384; tests, summary of a series of, 75.
Water, drinking, made potable, 198.
Watterston, C., and Shropshire, C. W., modern treatment of syphilis, 766.
Watson, Ernest M., lesions of the posterior urethra; their symptomatology, diagnosis, and treatment, 583.
Weil's disease, present knowledge of, 1037.
Welch, W. H., what the American soldier now fighting in France should know about tuberculosis; introduction to, 751.
Welfare work, publicity for city, 379.
